ABSTRACT

Locating the gamma-ray emission sites in blazar jets is a long standing and highly controversial issue. We jointly investigate several constraints on the distance scale \( r \) and Lorentz factor \( \Gamma \) of the gamma-ray emitting regions in luminous blazars (primarily flat spectrum radio quasars). Working in the framework of one-zone external radiation Comptonization models, we perform a parameter space study for several representative cases of actual gamma-ray flares in their multiwavelength context. We find a particularly useful combination of three constraints: from an upper limit on the collimation parameter \( \Gamma \theta \lesssim 1 \), from an upper limit on the synchrotron self-Compton (SSC) luminosity \( L_{\text{SSC}} \lesssim L_X \), and from an upper limit on the efficient cooling photon energy \( E_{\text{cool,obs}} \lesssim 100 \) MeV. These three constraints are particularly strong for sources with low accretion disk luminosity \( L_d \). The commonly used intrinsic pair-production opacity constraint on \( \Gamma \) is usually much weaker than the SSC constraint. The SSC and cooling constraints provide a robust lower limit on the collimation parameter \( \Gamma \theta \gtrsim 0.1–0.7 \). Typical values of \( r \) corresponding to moderate values of \( \Gamma \sim 20 \) are in the range \( 0.1–1 \) pc, and are determined primarily by the observed variability timescale \( t_{\text{var,obs}} \). Alternative scenarios motivated by the observed gamma-ray/millimeter connection, in which gamma-ray flares of \( t_{\text{var,obs}} \sim \) a few days are located at \( r \sim 10 \) pc, are in conflict with both the SSC and cooling constraints. Moreover, we use a simple light travel time argument to point out that the gamma-ray/millimeter connection does not provide a significant constraint on the location of gamma-ray flares.

We argue that spine-sheath models of the jet structure do not offer a plausible alternative to external radiation fields, as both the SSC and cooling constraints. Moreover, we use a simple light travel time argument to point out that the gamma-ray/millimeter connection does not provide a significant constraint on the location of gamma-ray flares. We argue that spine-sheath models of the jet structure do not offer a plausible alternative to external radiation fields at large distances; however, an extended broad-line region is an idea worth exploring. We propose that the most definite additional constraint could be provided by determination of the synchrotron self-absorption frequency for correlated synchrotron and gamma-ray flares.

1. INTRODUCTION

Blazars are a class of active galaxies whose broadband emission is dominated by non-thermal components produced in a relativistic jet pointing toward us (Urry & Padovani 1995). Due to the relativistic luminosity boost, many of these sources outshine their host galaxies by orders of magnitude, making them detectable at cosmological distances. The brightest blazars, belonging to the subclasses known as flat-spectrum radio quasars (FSRQs) and low-synchrotron-peaked BL Lacs (LBLs), radiate most of their energy in MeV/GeV gamma-rays (Fossati et al. 1998). The origin of this gamma-ray emission has been debated for a long time, with proposed mechanisms including external radiation Comptonization (ERC; Dermer et al. 1992; Sikora et al. 1994), synchrotron self-Comptonization (SSC; Maraschi et al. 1992; Bloom & Marscher 1996), and hadronic processes (e.g., Mannheim & Biermann 1992; Aharonian 2000; Mücke & Protheroe 2001). The emerging consensus favors the ERC process (Ghisellini et al. 1998; Mukherjee et al. 1999; Hartman et al. 2001; Sikora et al. 2009; Böttcher et al. 2013), especially for blazars with high-power jets (Meyer et al. 2012).

Several theoretical models have been proposed for energy dissipation and particle acceleration in relativistic blazar jets. To discriminate among these models, it is crucial to pinpoint the location along the jet where the bulk of the non-thermal radiation is produced. Several lines of argumentation have led blazar researchers to answers varying by almost three orders of magnitude.

Gamma-ray radiation at GeV energies can escape from the quasar environment, avoiding absorption, if it is produced at distances from the central engine \( r \gtrsim 0.01 \) pc (Ghisellini & Madau 1996). At these smallest allowed distances, the dominant external radiation component in the jet co-moving frame is the direct emission of the accretion disk (e.g., Dermer & Schlickeiser 2002). At distances of \( r \sim 0.1 \) pc, the co-moving external radiation is dominated by broad emission lines (BEL; e.g., Sikora et al. 1994). For an emitting region propagating with a typical Lorentz factor of \( \Gamma \sim 20 \), the observed variability timescale \( t_{\text{var}} \sim r/\Gamma^2 c \) expected from radiation produced at such distances is several hours, which is consistent with the shortest variability timescales probed by the Fermi Large Area Telescope (LAT; Tavecchio et al. 2010; Saito et al. 2013; Rani et al. 2013). The likely dissipation mechanism at these distances depends on the efficiency of energy flux conversion from magnetic (Poynting flux) to inertial (kinetic energy flux) forms (Sikora et al. 2005). In particle-dominated jets, internal shocks can operate with reasonable efficiency, provided that the jet acceleration mechanism is strongly modulated (Spada et al. 2001). In magnetically dominated jets, shocks are generally expected to be weak (but see Komissarov 2012), however, in the right circumstances the jet magnetic fields could be dissipated.

4 NASA Einstein Postdoctoral Fellow.
directly in the process of magnetic reconnection (e.g., Giannios & Spruit 2006; Giannios et al. 2009).

At distances of \( r \gtrsim 1 \) pc, external radiation fields are dominated by the infrared (IR) thermal radiation emitted by hot dust (Blazeviljski et al. 2000). The gamma-ray radiation produced at these distances is expected to vary over a few days. The associated synchrotron radiation should be transparent at wavelengths \( \lambda_{\text{syn, obs}} \lesssim 1 \) mm, and in some sources a fairly good correlation was observed between the optical and millimeter signals (e.g., Sikora et al. 2008), or between the gamma-ray and millimeter signals (e.g., Wehrle et al. 2012). At these distances, reconnection shocks arising from the interaction of the jet with the external medium provide an alternative dissipation mechanism (e.g., Nalewajko 2012).

The structure of blazar jets can be at least partially resolved with interferometric radio/millimeter observations. Typically, it includes a stationary core and a succession of knots propagating superluminally downstream from the core. The core could be a photosphere due to the synchrotron self-absorption (SSA) process (certainly at wavelengths longer than 7 mm), or an optically thin physical structure presumably resulting from reconnection shocks (Marscher 2009). There is substantial evidence that many major gamma-ray flares in blazars are accompanied by radio/millimeter outbursts, and/or ejection (estimated moment of passing through the apparent position of the core) of superluminal radio/millimeter knots (e.g., Marscher et al. 2012). While radio/millimeter outbursts are typically much longer (~weeks/months) than gamma-ray flares (~hours/days), the gamma-ray flares are often found between the onset and the peak of the millimeter outbursts (Lähteenmäki & Valtaoja 2003; León-Tavares et al. 2011). This gamma-ray/millimeter connection is used to argue for gamma-ray flares being produced at distance scales of \( r \sim 10–20 \) pc (e.g., Agudo et al. 2011a, 2011b; see also Sikora et al. 2008). At these distances, the external radiation field is still likely dominated by thermal dust emission, although its energy density is expected to fall off rapidly with \( r \).

In this work, we study the parameter space of location \( r \) and Lorentz factor \( \Gamma \) of the emitting regions responsible for major gamma-ray flares in luminous blazars.\(^5\) We use five direct observables—gamma-ray luminosity \( L_{\gamma} \), gamma-ray variability timescale \( \tau_{\text{var, obs}} \), synchrotron luminosity \( L_{\text{syn}} \) (or the Compton dominance parameter \( q = L_{\gamma}/L_{\text{syn}} \)), X-ray luminosity \( L_X \), and accretion disk luminosity \( L_d \)—and a minimal number of assumptions—in particular the Doppler-to-Lorentz factor ratio \( D/\Gamma \), and the external radiation sources covering factors \( \xi_{\text{BLR}}, \xi_{\text{SH}} \)—to derive four constraints in the \((r, \Gamma)\) plane related to the following parameters—collimation parameter \( \Gamma_\theta \), synchrotron self-Compton luminosity \( L_{\text{SSC}} \), observed ERC photon energy corresponding to efficient electron cooling threshold \( E_{\text{cool, obs}} \), and observed ERC photon energy corresponding to intrinsic pair-production absorption threshold \( E_{\text{max, obs}} \)—and two predictions for the following parameters—SSA characteristic observed wavelength \( \lambda_{\text{SSA, obs}} \), and minimum required jet power \( L_{\text{j, min}} \). These constraints are then applied in several case studies of actual gamma-ray flares of prominent blazars for which detailed multiwavelength data are available, and for which all five observables can be securely estimated. Most of these cases have already been discussed in the literature, but here they are systematically and critically compared for the first time.

We begin by deriving our constraints in Section 2, followed by additional predictions in Section 3. Then we present the case studies in Section 4. We consider the sensitivity of our constraints to the most uncertain parameters in Section 5. Our results are discussed in Section 6 and summarized in Section 7.

2. CONSTRAINTS ON \( r \) AND \( \Gamma \)

We consider an emitting region located at a distance \( r \) from the central supermassive black hole (SMBH), propagating with velocity \( \beta = v/c \) and Lorentz factor \( \Gamma = (1 - \beta^2)^{-1/2} \). Parameters measured in the co-moving frame of the emitting region will be denoted with a prime. We should stress here that the Lorentz factor of the emitting region \( \Gamma \) does not need to coincide with the jet Lorentz factor \( \Gamma_j \). While simple models explicitly assume that \( \Gamma \approx \Gamma_j \), in some scenarios a significant difference between these values is inferred, e.g., in the spine-sheath model (Ghisellini et al. 2005) and in the mini-jet model (Giannios et al. 2009).

For an observer located at a viewing angle \( \theta_{\text{obs}} \), with respect to the emitting region velocity vector, the Doppler factor of the observed radiation is \( D = [\Gamma(1 - \beta \cos \theta_{\text{obs}})]^{-1} \). In blazars, the value of \( D \) is of the same order as \( \Gamma \), but the actual ratio \( D/\Gamma \) is a major source of uncertainty in constraining \( r \) and \( \Gamma \). In the case of a very compact emitting region, for \( \theta_{\text{obs}} \approx 1/\Gamma \) we have \( D/\Gamma \approx 1 \), and for \( \theta_{\text{obs}} \approx 0 \) we have \( D/\Gamma \approx 2 \). However, in a conical jet, elements of the emitting region may span a significant range of \( \theta_{\text{obs}} \), and thus a significant range of \( D/\Gamma \).

The effective value of \( D/\Gamma \) depends not only on the mean \( \theta_{\text{obs}} \) of the emitting region, but also on its opening angle \( \theta \). In particular, for emitting regions with \( \Gamma \theta \approx 1 \), we expect that \( D/\Gamma \lesssim 1 \).

The values of \( \Gamma_j \) and \( D \) for individual sources can be evaluated independently by analyzing the radio structure of jets observed with very long baseline interferometry (VLBI) techniques (Jorstad et al. 2005), and many such results are available for the MOJAVE sample (Hovatta et al. 2009). Therefore, it is now possible to make an informed choice of \( D/\Gamma_j \) for many studied sources. However, as we will discuss later, this does not work equally well for all sources. In this work, we decided to adopt \( D/\Gamma_j = 1 \) for all analyzed sources, and we evaluate the effect of varying the value of \( D/\Gamma \) in Section 5.

2.1. Collimation Constraint

We assume that the emitting region has a characteristic size \( R \), which is related to the co-moving variability timescale \( \tau_{\text{var}} \approx c t_{\text{var}} \). The variability timescales scale like \( \tau_{\text{var}} = D t_{\text{var, obs}}/(1+z) \), where \( z \) is the blazar redshift. The most reliable estimate of the observed variability timescale \( t_{\text{var, obs}} \) is the flux-doubling timescale measured with respect to the flare peak. We can also relate \( R \) to the location of the emitting region via \( R \approx \theta r \). Again, we distinguish \( \theta \) from the jet opening angle \( \theta_j \), demanding only that \( \theta \lesssim \theta_j \). It is convenient to combine \( \theta \) with the Lorentz factor \( \Gamma \) to define the collimation parameter \( \Gamma \theta \). We can now write the source Lorentz factor as a function of \( \Gamma \theta \):

\[
\Gamma(r, \Gamma \theta) \approx \left( \frac{D}{\Gamma} \right)^{1/2} \left[ \frac{(1+z)(\Gamma \theta) r}{c t_{\text{var, obs}}} \right]^{1/2}.
\]

There are strong observational and theoretical indications that \( \Gamma \theta_j < 1 \) for blazar jets. A jet opening angle on a scale of tens of parsecs was measured in a substantial sample

\(^5\) In some blazar studies, multiple emitting regions were deemed necessary (e.g., Nalewajko et al. 2012b). However, in any case where a coherent gamma-ray flare is observed, one can consider only the emitting region dominating the gamma-ray emission.
of blazars using VLBI imaging, with the typical result of \( \Gamma \theta_0 \sim 0.1-0.2 \) (Pushkarev et al. 2009; Clausen-Brown et al. 2013). Numerical simulations of acceleration and collimation of external-pressure-supported relativistic jets also find that after the acceleration is complete, \( \Gamma \theta_0 \lesssim 1 \) (Komissarov et al. 2009; Tchekhovskoy et al. 2010). However, the relation between the collimation parameter of the jet \( \Gamma \theta_0 \) and the collimation parameter of the emitting region \( \Gamma \) is unclear. On one hand, we expect that \( \theta \lesssim \theta_0 \), but on the other hand, it is possible that \( \Gamma > \Gamma_0 \). Therefore, here we adopt a relatively conservative collimation constraint, defined as \( \Gamma \theta_0 \lesssim 1 \).

2.2. SSC Constraint

We assume that the gamma-ray emission is produced by Comptonization of external radiation (ERC) by a population of ultrarelativistic electrons, and that the apparent gamma-ray luminosity \( L_{\gamma} \) (hereafter understood as the peak of the SED) is related to the bolometric luminosity \( L_{\gamma, \text{bol}} = \int L_{\gamma, \nu} d\nu \) measured by Fermi/LAT. The peak luminosity of the ERC component, \( L_{\gamma, \text{bol}} \), represents the collision of the underlying ultrarelativistic electrons. The synchrotron and the SSC components, of which at least the former should contribute to the observed SEDs as indicated by fast optical/IR flares, are often well correlated with the gamma rays. The three luminosities—\( L_{\text{ERC}}, L_{\text{SSC}}, L_{\gamma} \)—can be related to the co-moving energy densities of external radiation \( u_{\gamma} \), magnetic fields \( B_{\gamma} \), and synchrotron radiation \( u_{\gamma, \text{SSC}} \), respectively. On one hand, we have \( L_{\text{SSC}} = (L_{\text{SSC}}/L_{\gamma, \text{SSC}}^0) = 3/4 \) is a bolometric correction factor (mainly due to spectral shape and source geometry). On the other hand, we can define a Compton dominance parameter

\[
q = \frac{L_{\gamma}}{L_{\gamma, \text{syn}}} \approx \frac{\gamma_{\text{syn}}(\Gamma_{\text{syn}})}{u_{\gamma}} \simeq \frac{L_{\gamma}}{u_{\gamma}} \approx \frac{\Gamma_{\gamma}^2 L_{\gamma}}{3 \pi c^2 r^2},
\]

where \( \gamma_{\text{syn}} = (L_{\text{SSC}}/L_{\gamma})/(L_{\text{SSC, bol}}/L_{\gamma, \text{bol}}) \approx 1/2 \) is a bolometric correction factor (mainly due to Klein–Nishina effects), and the \( (\Gamma_{\text{syn}}/2) \) factor reflects the beaming profile of the SSC component in the case of flat \( v \), SED (Dermer 1995). The co-moving energy density of external radiation is related to the accretion disk luminosity \( L_{\text{bol}} \) via

\[
u_{\gamma} \simeq \frac{\gamma(r) \Gamma_{\text{SSC}}^2 L_{\gamma}}{3 \pi c^2 r^2},
\]

where \( \gamma(r) \) is a function that describes the composition of external radiation fields, including contributions from the broad-line region (BLR), the dusty torus producing infrared emission (IR), and the direct accretion disk radiation:

\[
\gamma(r) \simeq \frac{0.4 \xi_{\text{BLR}}(r/r_{\text{BLR}})^2}{1 + (r/r_{\text{BLR}})^{4}} + \frac{0.4 \xi_{\text{IR}}(r/r_{\text{IR}})^2}{1 + (r/r_{\text{IR}})^{4}} + \frac{0.21 R_g}{r},
\]

where \( \xi_{\text{BLR}} \) is the covering factor of the BLR of characteristic radius \( r_{\text{BLR}} \), \( \xi_{\text{IR}} \) and \( r_{\text{IR}} \) are the analogous parameters of the dusty torus, and \( R_g \) is the gravitational radius of the SMBH (we explain the origin of this function in Appendix A). In this work, we adopt the following scaling laws: \( r_{\text{BLR}} \lesssim 0.1 L_{\text{bol}}^{1/2} \), pc, and \( r_{\text{IR}} \lesssim 2.5 L_{\text{bol}}^{1/2} \), pc, where \( L_{\text{bol}} = L_{\text{bol}} \times 10^{46} \text{ erg s}^{-1} \) (Sikora et al. 2009). Putting the above relations together, we obtain a constraint on \( \Gamma \):

\[
\Gamma(r, L_{\gamma}) \simeq \left[ \frac{3}{L_{\gamma}} \left( \frac{L_{\gamma}}{L_{\gamma, \text{SSC}}^0} \right) \left( \frac{L_{\gamma}}{L_{\gamma, \text{syn}}^0} \right) \right]^{1/8} \times \left[ \frac{D}{r} \right]^{-\frac{1}{4}} \left[ \frac{(1+z)r}{2c t_{\text{var, obs}}} \right]^{1/4}.
\]

The SSC component in the SEDs of luminous blazars peaks at the observed photon energy of \( E_{\text{SSC, obs}} \simeq 20 \text{ neV} \times D B_{\gamma, \text{peak}}^4/(1+z) \), where \( B_{\gamma} = B_{\gamma}/(1 \text{ G}) \) and \( \gamma_{\text{peak}} \) is the characteristic random Lorentz factor of electrons contributing to the SSC peak. We can estimate \( \gamma_{\text{peak}} \) from the observed photon energy of the SED peak of the ERC component \( E_{\text{ERC, obs}} \simeq D \gamma_{\text{peak}}^2 E_{\text{ext}}(r)/(1+z) \), where \( E_{\text{ext}}(r) \) is the energy of external radiation photons. In order to take into account the transition between the BLR and IR external radiation fields, we use the following approximation (see Appendix A):

\[
E_{\text{ext}}(r) \simeq \frac{E_{\text{BLR}}}{1 + (r/r_{\text{BLR}})^{3/2}} + \frac{E_{\text{IR}}}{1 + (r/r_{\text{IR}})^{3/2}},
\]

where \( E_{\text{BLR}} \simeq 10 \text{ eV} \) and \( E_{\text{IR}} \simeq 0.3 \text{ eV} \). The magnetic field strength can be found from Equations (2) and (3):

\[
B_{\gamma} \simeq D \left[ \frac{8 \xi_{\text{SSC}} \xi_{\gamma}(r) L_{\gamma}}{3 q c} \right]^{1/2}.
\]

Combining the above formulas, we find:

\[
E_{\text{SSC, obs}} \simeq \frac{20 \text{ neV} \times (1+z)}{r} \left[ \frac{E_{\text{SSC, obs}}}{E_{\text{ext}}(r)} \right]^{1/2} \times \left[ \frac{8 \xi_{\text{SSC}} \xi_{\gamma}(r) L_{\gamma}}{3 q c} \right].
\]

One can see that \( E_{\text{SSC, obs}} \) is a sensitive function of \( E_{\text{SSC, obs}} \) and \( \Gamma \). However, for \( \Gamma = 20 \), \( E_{\text{SSC, obs}} = 100 \text{ MeV} \), \( r = 1 \text{ pc} \), \( E_{\text{ext}} = 1 \text{ eV} \), \( \xi = 0.1 \), \( L_{\gamma} = 3 \times 10^{45} \text{ erg s}^{-1} \), and \( q = 10 \), we find \( E_{\text{SSC, obs}} \simeq 6(1+z) \) keV. Because SSC spectral components are very broad, in most cases they should peak around, or contribute significantly to, the soft/hard X-ray background. Some blazars show spectral softening in the soft X-ray part of their SEDs, which was interpreted as a signature of the SSC component (Bonnoli et al. 2011). However, in many sources the observed X-ray emission is harder than it would be if it were dominated by the SSC component (Sikora et al. 2009). Also, the observed X-ray variability is usually not well correlated with variability in the gamma-ray and optical bands (Hayashida et al. 2012). In the case that the SSC component dominates the X-ray emission, we would expect that X-ray variability should be stronger than the optical/IR variability. For example, in a simple scenario of varying number of energetic electrons at constant magnetic field we have \( L_{\gamma} \propto L_{\gamma, \text{syn}}^2 \). As this is not the case for luminous blazars, we can only use the observed X-ray luminosity as an upper limit for the SSC luminosity (Ackermann et al. 2010). Therefore, our SSC constraint is defined as \( L_{\gamma} \lesssim L_{\gamma} \).

2.3. Cooling Constraint

Rapid gamma-ray variability of blazars, with roughly time-symmetric light curve peaks, and tight energetic requirements for the brightest observed gamma-ray flares, indicate very efficient cooling of the underlying ultrarelativistic electrons. The
radiative cooling of electrons in luminous blazars is dominated by the ERC process with a cooling timescale $t_{\text{cool}}(y) \simeq 3m_ec/(4\gamma \gamma \mu_{\text{ext}})$, where $\gamma$ is the electron random Lorentz factor. In general, $t_{\text{cool}}(y)$ should be compared with the variability timescale $t_{\text{var}}$ (which is associated with the observed flux doubling timescale; see Section 2.1), and adiabatic cooling timescale $t_{\text{ad}}$. Observations of roughly time-symmetric flares indicate that the cooling timescales do not exceed the observed flux decaying timescales, i.e., that $t_{\text{cool}}(y) \lesssim t_{\text{var}}$. We calculate a characteristic electron Lorentz factor $\gamma_{\text{cool}}$ such that $t_{\text{cool}}(\gamma_{\text{cool}}) \simeq t_{\text{var}}$ and a corresponding observed ERC photon energy $E_{\text{cool,obs}} \simeq \Delta \Gamma_{\text{cool}} E_{\text{ext}}(r)/(1 + z)$. Taking the above together, we obtain the following constraint on $\Gamma$:

$$
\Gamma(r, E_{\text{cool,obs}}) \simeq \left( \frac{D}{\Gamma} \right)^{-1/4} \left[ \frac{9 \pi m_e c^2 r^2}{4 \gamma \Gamma \zeta(r) L_{\text{d, var,obs}}} \right]^{1/2} \times \left( \frac{E_{\text{cool,obs}}}{L_{\text{cool}}} \right)^{1/4}.
$$

(9)

Since the gamma-ray light curves based on the Fermi/LAT data are typically calculated for photon energies $E > 100$ MeV, our cooling constraint is defined as $E_{\text{cool,obs}} \lesssim 100$ MeV.

Alternatively, the cooling timescale as a function of photon energy potentially can be estimated directly from gamma-ray observations, but this is only feasible for the very brightest events (Dotan et al. 2012).

### 2.4. Internal Gamma-Ray Opacity Constraint

The maximum observed gamma-ray photon energy $E_{\text{max,obs}}$ is constrained at least by the pair-production absorption process due to soft radiation produced in the same emitting region (e.g., Dondi & Ghisellini 1995). The peak cross section for the pair-production process is $\sigma_{\gamma \gamma} \simeq \sigma_{\gamma}/5$ for soft photons of co-moving energy $E'_{\text{soft}} \simeq 3.6(m_e c^2)^2/E_{\text{max}}$. In the observer frame, the soft photon energy is

$$
E_{\text{soft,obs}} \simeq \frac{3.6(m_e c^2)^2 D^2}{(1 + z)^2 E_{\text{max,obs}}} \simeq \frac{38 \text{ keV}}{(1 + z)^2} \left( \frac{E_{\text{max,obs}}}{10 \text{ GeV}} \right)^{-1} \left( \frac{D}{20} \right)^2.
$$

(10)

The optical depth for gamma-ray photons is:

$$
\tau_{\gamma \gamma} \simeq \sigma_{\gamma \gamma} n_{\text{soft}} R \simeq \frac{(1 + z)^2 \sigma_{\gamma} L_{\text{soft,obs}} E_{\text{max,obs}}}{72 \pi (m_e c^2)^2 \gamma^2 \Gamma_{\text{var,obs}}}.
$$

(11)

As the observed soft photon energy $E_{\text{soft,obs}}$ may fall outside any observed energy range, we relate the target soft radiation luminosity to the observed X-ray luminosity via a spectral index $\alpha$ such that

$$
L_{\text{soft}} = L_X \left( \frac{E_{\text{soft,obs}}}{E_X} \right)^{1-\alpha} \simeq \frac{[3.6(m_e c^2)^2]^{1-\alpha} D^2 - 2a L_X}{(1 + z)^2 E_X^{1-\alpha} E_{\text{max,obs}}^{1-\alpha}}.
$$

(12)

Substituting this into Equation (11), we obtain:

$$
\tau_{\gamma \gamma} \simeq \frac{(1 + z)^2 \sigma_{\gamma} L_{\text{soft,obs}} E_{\text{max,obs}}}{20 \pi [3.6(m_e c^2)^2 c^2 D^4 + 2a E_X^{1-\alpha} t_{\text{var,obs}}]}.
$$

(13)

For gamma-ray observations of blazars, it is typical to associate $E_{\text{max,obs}}$ with $\tau_{\gamma \gamma} \simeq 1$. This leads to the following constraint on $\Gamma$:

$$
\Gamma(r, E_{\text{max,obs}}) \simeq \left( \frac{(1 + z)^2 \sigma_{\gamma} L_X E_{\text{max,obs}}}{20 \pi [3.6(m_e c^2)^2 c^2 L_{\text{BLR}}]} \right)^{1/2} \left( \frac{D}{\Gamma} \right)^{-1}.
$$

(14)

In Section 4, we will demonstrate that the internal gamma-ray opacity constraint is relatively weak compared to the SSC constraint.

An additional potential source of gamma-ray opacity is from the BEL. To the first order of approximation, this would affect photons of observed energy:

$$
E_{\text{max,BEL,obs}} \simeq \frac{3.6(m_e c^2)^2}{(1 + z) E_{\text{BLR}}} \simeq \frac{94 \text{ GeV}}{(1 + z)} \left( \frac{E_{\text{BLR}}}{10 \text{ eV}} \right)^{-1},
$$

(15)

with the peak optical depth of

$$
\tau_{\gamma \gamma, \text{BEL}}(r) \simeq \frac{\xi_{\text{BLR}} \sigma_{\gamma} L_{\text{d,BLR}}}{20 \pi c r_{\text{d,BLR}}^2 E_{\text{BLR}}} \simeq 71 \left( \frac{\xi_{\text{BLR}}}{0.1} \right) \left( \frac{L_{\text{d}}}{10^{46} \text{ erg s}^{-1}} \right)^{1/2} \left( \frac{r_{\text{d,BLR}}}{r_{\text{BLR}}} \right) \left( \frac{E_{\text{BLR}}}{10 \text{ eV}} \right)^{-1}
$$

(16)

(again using the scaling $r_{\text{BLR}} \simeq 0.1 L_{\text{d, BLR}}$). The high value of the peak optical depth indicates that absorption should already become noticeable at the threshold observed energy of $(m_e c^2)^2/(1 + z) E_{\text{BLR}} \simeq 26 \text{ GeV}/(1 + z)/E_{\text{BLR}}/10 \text{ eV})$. The actual strength of the BLR absorption features depends significantly on the BLR geometry, and determining it requires detailed calculations (e.g., Donea & Protheroe 2003; Reimer 2007; Tavecchio & Ghisellini 2012). We will briefly comment on the expected significance of the BLR absorption in those cases from Section 4, which allow for the emitting region to be located within $r_{\text{BLR}}$.

### 3. PREDICTIONS FOR GIVEN $r$ AND $\Gamma$

#### 3.1. Synchrotron Self-absorption

Synchrotron radiation is subject to SSA process, which can produce a sharp spectral break. This is a powerful probe of the intrinsic radius of the source of synchrotron emission (e.g., Sikora et al. 2008; Barniol Duran et al. 2013). In the co-moving frame, the SSA break is expected at:

$$
\nu_{\text{SSA}} \simeq \frac{1}{3} \left( \frac{eB'}{m_e^2 c} \right)^{1/7} \frac{L_{\text{d, syn}}}{R_{\text{d, syn}}^{2/7}}.
$$

(17)

9 Considering the ionized Helium lines with $E_{\text{BLR}} \simeq 54 \text{ eV}$, the threshold observed energy would shift to $\simeq 4.8 \text{ GeV}/(1 + z)$ (Postan & Stern 2010); however, this is only relevant for distance scales $r \ll r_{\text{BLR}}$ that are not of interest here.
where we approximated the synchrotron luminosity at $v_{	ext{SSA}}$ with the synchrotron energy distribution peak luminosity $L_{\text{syn}}^\prime$ (i.e., we assumed a flat synchrotron SED in the mid-IR/millimeter band; in any case, $v_{	ext{SSA}}$ depends only weakly on the spectral index of unabsorbed synchrotron emission). Substituting relevant relations from previous sections, we find a constraint on $\Gamma$:

$$\Gamma(r, v_{\text{SSA}}, \text{obs}) \approx \left[ \frac{8 g_{\text{ERC}} e^2 \xi(r) L_d L_{\gamma}^\prime}{315 q^7 \beta^6 e^{-11} (1 + z) \beta_r^{14} v_{\text{SSA}, \text{obs}}^7 r^2} \right]^{1/8} \times \left( \frac{D}{\Gamma} \right)^{-1}.$$  

(18)

In luminous blazars, the SSA spectral break is typically observed in the sub-millimeter/radio band. As the synchrotron radiation observed in this band probes lower electron energies than the $\sim$ GeV gamma-ray radiation, a connection between these bands should be verified by studying variability correlations. These are very challenging observations, and for most cases studied in Section 4 such data are not available. Therefore, in this work, the SSA constraint is limited to provide a prediction of what $v_{\text{SSA}, \text{obs}}$ should be for each studied case.

### 3.2. Jet Energetics

We can constrain the energy content of blazar jets underlying the observed gamma-ray flares by estimating two of its essential ingredients: the radiation energy density dominated by the gamma rays $u_\gamma'$, and the magnetic energy density $u_B'$. Because the production of gamma-ray radiation through the ERC process is very efficient, $u_\gamma'$ closely probes the high-energy end of the electron energy distribution. Additional jet energy may be carried by cold/warm electrons and protons, the contribution of which is very uncertain. For example, the number of cold electrons can be constrained by modeling the broadband SEDs, but the low-energy electron distribution index is usually one of the most uncertain parameters. On the other hand, the energy content of protons in blazar jets can be constrained only indirectly, by combining arguments such as interpretation of (hard) X-ray spectra of luminous blazars, and energetic coupling between the protons and electrons (Sikora 2011). Rather than introducing extra parameters with highly uncertain values, we choose to discuss a firm lower limit $L_{\gamma, \text{min}}$ on the jet power required to produce the observed gamma-ray flares of blazars together with their synchrotron and SSC counterparts.

The radiation energy density can be written as:

$$u_\gamma' \approx \frac{L_{\gamma}}{4 \pi c D^4 R^2} \approx \left( \frac{D}{\Gamma} \right)^{-6} \frac{(1 + z)^2 L_{\gamma}}{4 \pi c \Gamma^2 r_{\text{var, obs}}^2}.$$  

(19)

The magnetic energy density $u_B'$ can be derived from the synchrotron luminosity $L_{\text{syn}}$, which is related to the gamma-ray luminosity $L_{\gamma}$ through the Compton dominance parameter $q = L_{\gamma}/L_{\text{syn}}$:

$$u_B' \approx \left( \frac{D}{\Gamma} \right)^2 \frac{g_{\text{ERC}} u_\gamma' \text{ext}}{q} \approx \left( \frac{D}{\Gamma} \right)^2 \frac{g_{\text{ERC}} (r) \Gamma^2 L_d}{3 \pi c q r^2}.$$  

(20)

Instead of using these two energy densities separately, we will analyze their more useful combinations: their ratio and their sum. The ratio of the two energy densities is a measure of energy equipartition between the magnetic fields and the ultra-relativistic electrons. One can show that (cf. Sikora et al. 2009):

$$\frac{u_\gamma'}{u_B'} \approx \frac{L_{\gamma} L_{\text{SSC}}}{g_{\text{SSC}} L_{\text{syn}}^2},$$

(21)

therefore, this energy density ratio is proportional to $L_{\text{SSC}}$, and it follows the same dependence on $r$ and $\Gamma$. The sum of the two energy densities constitutes a lower limit on the jet energy density $u_{\gamma, \text{min}}' = u_\gamma' + u_B'$. The corresponding minimum jet power is given by $L_{\gamma, \text{min}} \approx \pi c \Gamma^2 R^2 u_{\gamma, \text{min}}'$. Therefore, we can write $L_{\gamma, \text{min}} = L_{\gamma, j; \text{min}} + L_{\gamma, B; \text{min}}$, where

$$L_{\gamma, j; \text{min}} = \left( \frac{D}{\Gamma} \right)^{-4} \frac{L_{\gamma}}{4 R^2},$$

(22)

$$L_{\gamma, B; \text{min}} = \left( \frac{D}{\Gamma} \right)^{-4} g_{\text{ERC}} \left( \frac{r}{3 q} \right) L_d \left[ \frac{c t_{\text{var, obs}}}{r (1 + z)} \right]^2.$$  

(23)

The dependence of the magnetic jet power on $\Gamma$ is much steeper than for the radiative jet power. Thus, we can derive approximate constraints on $\Gamma$ in two limits. For $u_\gamma' \gg u_B'$, we find

$$\Gamma(L_{\gamma, j, \text{min}}) = \left( \frac{D}{\Gamma} \right)^{-2} \left( \frac{L_{\gamma}}{4 L_{\gamma, j; \text{min}}} \right)^{1/2},$$

(24)

and for $u_\gamma' \ll u_B'$, we find

$$\Gamma(L_{\gamma, B; \text{min}}) = \left( \frac{D}{\Gamma} \right)^{-2/3} \left( \frac{3 q L_{\gamma, B; \text{min}}}{g_{\text{ERC}} (r) L_d} \right)^{1/6} \times \left( \frac{r (1 + z)}{c t_{\text{var, obs}}} \right)^{1/3}.$$  

(25)

In Section 4, we will investigate the values of $u_\gamma'/u_B'$ and $L_{\gamma, \text{min}}$ for individual blazar flares. Again, we stress that contributions from cold/warm electrons and protons should be included to obtain total jet energies.

### 4. CASE STUDIES

In this section, we apply the constraints derived in Section 2 to several well-studied cases of powerful gamma-ray flares in blazars with excellent multiwavelength coverage. We emphasize the value of having extensive simultaneous spectral coverage of these sources; however, each case is different and the data quality is not uniform enough to warrant a broader study.

#### 4.1. 3C 454.3 at MJD 55520

3C 454.3 ($\alpha = 0.859$, $d_L \approx 5.49$ Gpc) provided us with the most spectacular gamma-ray flares in the Fermi era (Nalewajko et al. 2013). On MJD 55520 (2010 Nov 20) it produced a flare of apparent bolometric ($E > 100$ MeV) luminosity of $L_{\gamma, \text{bol}} \approx 2.1 \times 10^{39}$ erg s$^{-1}$ (Abdo et al. 2011). We convert the bolometric peak luminosity $L_{\gamma, \text{bol}}$ into the peak $\nu L_\nu$ luminosity $L_{\nu}$, using a bolometric correction factor $g_{\gamma, \text{bol}} = L_{\gamma, \text{bol}}/L_{\gamma} \approx 4.5$ calculated from the best-fit spectral model (power-law with exponential cutoff), resulting in $L_{\gamma} \approx 4.7 \times 10^{39}$ erg s$^{-1}$. The flare temporal template fitted by Abdo et al. (2011) has a flux doubling timescale of $t_{\text{var, obs}} \approx 8.7 \ h \approx 3.13 \times 10^4 \ s$. Vercellone et al. (2011) showed that this gamma-ray flare was accompanied by simultaneous outbursts, smaller in amplitude by a factor $\sim 3$, in soft X-ray, optical, and millimeter bands. They compiled an SED from which we can estimate the simultaneous luminosity ratios $q = L_{\gamma}/L_{\text{syn}} \approx 30$, $L_{\text{syn}}/L_{\gamma} \approx 10$. These...
ratios are used to derive the simultaneous soft X-ray luminosity \( L_X \simeq 1.6 \times 10^{47} \text{ erg s}^{-1} \). We can also estimate the spectral index of the X-ray part of the spectrum as \( \alpha \simeq 0.65 \). The bolometric accretion disk luminosity is taken as \( L_d \simeq 6.75 \times 10^{46} \text{ erg s}^{-1} \) (Bonnoli et al. 2011), from which we find the characteristic radii of external radiation components \( r_{\text{BLR}} \simeq 0.26 \text{ pc} \) and \( r_{\text{IR}} \simeq 6.5 \text{ pc} \). The black hole mass of 3C 454.3 is uncertain; here we adopt the value of \( M_{\text{BH}} \sim 5 \times 10^7 M_\odot \) after Bonnoli et al. (2011).

In Figure 1, we plot the constraints on \( r \) and \( \Gamma \) corresponding to fixed values of \( \Gamma \theta, L_{\text{SSC}}, E_{\text{cool}, \text{obs}}, \lambda_{\text{SSA}, \text{obs}} \) and \( E_{\text{max}, \text{obs}} \), as well as the energetics parameters \( u'/u_B' \) and \( L_{j, \text{min}} \). We assumed here that \( \xi_{\text{BLR}} \simeq \xi_{\text{IR}} \simeq 0.1 \). The yellow area is defined by the following three conditions: \( \Gamma \theta < 1, L_{\text{SSC}} < L_X \), and \( E_{\text{cool}, \text{obs}} < 100 \text{ MeV} \). The intersection of the first two of these constraints gives the *marginal solution*—the minimum Lorentz factor \( \Gamma_{\text{min}} \simeq 30 \) and the minimum distance scale \( r_{\text{min}} \simeq 0.16 \text{ pc} \). For \( (r_{\text{min}}, \Gamma_{\text{min}}) \), other constraints yield the following predictions: \( \lambda_{\text{SSA}, \text{obs}} \simeq 125 \mu\text{m} \), \( E_{\text{max}, \text{obs}} \gtrsim 10 \text{ TeV} \), \( u'/u_B' \simeq 3.3 \), and \( L_{j, \text{min}} \simeq 1.7 \times 10^{46} \text{ erg s}^{-1} \simeq 0.25 L_d \).

On the other hand, in the IR region \( (r \sim r_{\text{IR}}) \), the SSC constraint is much stronger and hence there are no solutions with \( \Gamma < 50 \). Therefore, in this case, the dissipation region is clearly constrained to be located not far from \( r_{\text{BLR}} \). The minimum required jet power is one order of magnitude higher than the kinetic jet power estimated by Meyer et al. (2011).

VLBI measurements of the jet of 3C 454.3 yield \( D \simeq 20, \theta \simeq 33 \) (Hovatta et al. 2009), and \( \Gamma \theta \simeq 0.3 \) (Pushkarev et al. 2009). Adopting \( D/\Gamma \simeq 1.67 \) would shift the marginal solution to \( r_{\text{min}} \simeq 0.09 \text{ pc} \) and \( \Gamma_{\text{min}} \simeq 18 \). The VLBI-derived solution of \( r \simeq 0.34 \text{ pc} \) and \( \Gamma \simeq 20 \) would be consistent with our \( E_{\text{cool}, \text{obs}} \) constraint, and marginally consistent with our \( L_{\text{SSC}} \) constraint. On the other hand, for \( D/\Gamma = 1 \), the SSC constraint also implies that jet collimation parameter is \( \Gamma \theta > 0.5 \).

Abdo et al. (2011) estimated the minimum Doppler factor of the emitting region responsible for this flare as \( D_{\text{min}} \simeq 16 \), using the gamma-ray opacity constraint for the maximum observed photon energy of \( E_{\text{max}, \text{obs}} = 31 \text{ GeV} \). Our opacity constraint for the same \( E_{\text{max}, \text{obs}} \) yields \( \Gamma_{\text{min}} = D_{\text{min}} \simeq 13 \). The main reason for this discrepancy is that we use the 3.6 factor in Equation (10), which is neglected in numerous studies. We point out that the SSC constraint is stronger than the opacity constraint (see Ackermann et al. 2010). We also note that our minimum distance scale is compatible with the estimate of \( r_{\text{min}} \simeq 0.14 \text{ pc} \) obtained by calculating gamma-ray opacity due to the broad-line photons (Abdo et al. 2011).

The SSA break is predicted to fall in the far-IR range, both at the BLR and IR distance scales. 3C 454.3 was observed by Herschel/PACS and SPIRE instruments during and after the peak of this gamma-ray flare (Wehrle et al. 2012). While the period of the highest gamma-ray state was sparsely covered in the far-IR band, a very good correlation between the 160 \( \mu \text{m} \) data and the Fermi/LAT gamma rays was found. Such a correlation implies that the gamma-ray producing region is transparent to SSA, i.e., that \( \lambda_{\text{SSA}, \text{obs}} \gtrsim 160 \mu\text{m} \). Such a condition can be easily satisfied, together with our collimation and SSC constraints, even at BLR distance scales. However, Wehrle et al. (2012) also showed that 1.3 mm data from SMA, of much better sampling rate, correlate well with the gamma rays. This is very difficult to explain in a one-zone model—the 1.3 mm SSA line satisfies...
data presented in Figure 10 of Wehrle et al. (2012) indicate
December 3), also attracted considerable interest (e.g., Pacciani
for PKS 1510-089 by Nalewajko et al. (2012b).

... scales. This scenario is similar to the one proposed
observed increase of the 1 mm flux is \( t_{\text{var,min}} \approx 7.5 \) d.
Adopting this variability timescale, the 1 mm photosphere
can be located already at \( r_{\text{mm}} \approx 5 \) pc and \( \Gamma \approx 38 \),
which are much more reasonable parameters. Therefore, we need
to consider an extended, possibly structured emitting region
for the gamma rays observed during this event, with the rapidly flaring
component produced at sub-parsec scales, and a more slowly
varying component correlated with the 1 mm emission at
supra-parsec scales. This scenario is similar to the one proposed
for PKS 1510-089 by Nalewajko et al. (2012b).

Figure 2. Parameter space of \( r \) and \( \Gamma \) for the major flare of 3C 454.3 that peaked at MJD 55168. See Figure 1 for a detailed description. The diamond indicates the solution obtained by Bonnoli et al. (2011).

(A color version of this figure is available in the online journal.)

all three constraints only at \( r \approx 27 \) pc and \( \Gamma \approx 400 \). The most
reasonable way to accommodate this observation is to consider a
different variability timescale of the 1.3 mm emission. Indeed,
data presented in Figure 10 of Wehrle et al. (2012) indicate
that the flux-doubling timescale corresponding to the fastest
observed increase of the 1.3 mm flux is \( t_{\text{var,min}} \approx 7.5 \) d.

The apparent peak bolometric gamma-ray luminosity was \( L_{\gamma,\text{bol}} \approx 3.8 \times 10^{49} \) erg s\(^{-1}\) (Ackermann et al. 2010),
which corresponds to the \( \nu L_{\nu} \) luminosity \( L_{\nu} = L_{\gamma,\text{bol}}/\nu_{\gamma,\text{bol}} \approx 8.4 \times 10^{48} \) erg s\(^{-1}\). The variability timescale was estimated at \( t_{\text{var,obs}} \approx 1 \) d, al-
though episodes were observed with a flux-doubling timescale
as short as \( \approx 2.3 \) h. From the SED compiled by Bonnoli et al.
(2011), we deduce \( q = L_{\nu}/L_{\text{syn}} \approx 14 \); \( L_{\text{syn}}/L_{\text{X}} \approx 10 \),
and \( \alpha \approx 0.55 \). We use the same values of \( \xi_{\text{BLR}}, \xi_{\text{IR}}, L_{\alpha}, \) and \( M_{\text{BH}} \) as
for the MJD 55520 flare.

Our constraints for this event are shown in Figure 2. We find
the marginal solution at \( t_{\text{min}} \approx 0.17 \) pc and \( \Gamma_{\text{min}} \approx 19 \). This solution corresponds to \( \lambda_{\text{SSA,obs}} \approx 215 \) \( \mu \)m, \( u_{\gamma}^{\prime}/u_{B}^{\prime} \approx 1.6 \),
and \( L_{\gamma,\text{min}} \approx 10^{46} \) erg s\(^{-1}\) \( \approx 0.14 \) \( L_{\odot} \). While solutions within
\( r_{\text{BLR}} \) are allowed, the maximum observed photon energy
\( E_{\text{max,obs}} \approx 21 \) GeV (Ackermann et al. 2010), so the effect
of BLR absorption is expected to be lower than in the case of the
MJD 55520 flare (Section 4.1).

Bonnoli et al. (2011) modeled the SEDs of 3C 454.3 for
several epochs close to MJD 55168, probing different luminosity
levels. They noted that the gamma-ray luminosity scales with
the X-ray and UV luminosities roughly as \( L_{\gamma} \propto L_{\text{X}}^{2} \propto L_{\text{UV}}^{2} \).
Therefore, they proposed that the location of the gamma-
ray emitting region shifts outward with increasing gamma-
ray luminosity. For the highest state at MJD 55168, they
suggested a distance scale of \( r \approx 0.06 \) pc at \( \Gamma \approx 20 \) (see Figure 2).
It is critical to note at this point that they adopted a
variability timescale of \( t_{\text{var,obs}} \approx 6 \) hr and a Doppler-to-Lorentz
factor ratio of \( D/\Gamma \approx 1.45 \). We have checked that for such
parameters our constraints are marginally consistent with their
result; our model predicts \( u_{\gamma}^{\prime}/u_{B}^{\prime} \approx 0.84 \), \( \lambda_{\text{SSA}} \approx 118 \) \( \mu \)m,
and \( L_{\gamma,\text{min}} \approx 2.7 \times 10^{45} \) erg s\(^{-1}\).

4.3. AO 0235+164 at MJD 54760

AO 0235+164 (\( z \approx 0.94 \), \( d_{L} \approx 6.14 \) Gpc) is an LBL-type
blazar, which was active in 2008–2009. The highest gamma-ray
state, achieved between MJD 54700 and MJD 54780, was ana-
lyzed in detail by Ackermann et al. (2012). They estimated the
observed gamma-ray luminosity as \( L_{\gamma} \approx 6.7 \times 10^{47} \) erg s\(^{-1}\); the
observed variability timescale \( t_{\text{var,obs}} \approx 3 \) d \( \approx 2.6 \times 10^{5} \) s; the
Compton dominance \( q = L_{\gamma}/L_{\text{syn}} \approx 4 \); the synchrotron to
X-ray luminosity ratio \( L_{\text{syn}}/L_{\text{X}} \approx 6 \); and the characteristic radii of ex-
ternal radiation components \( r_{\text{BLR}} \approx 0.06 \) pc and \( r_{\text{IR}} \approx 1.6 \) pc.
For the black hole mass, they adopted \( M_{\text{BH}} \approx 4 \times 10^{8} \) \( M_{\odot} \).
The X-ray spectral index is very uncertain, as very soft X-ray spectra
were observed by \( \text{Swift}/X\)-ray Telescope during the gamma-ray
activity. Here we adopt \( \alpha \approx 1 \).
In Figure 3, we plot the constraints on the location of the gamma-ray flare, adopting $\xi_{\text{BLR}} = \xi_{\text{IR}} = 0.1$. The marginal solution is located at $r_{\text{min}} \simeq 0.65$ pc and $\Gamma_{\text{min}} \simeq 22$. The predictions for this solution are $\lambda_{\text{SSA,obs}} \simeq 920$ \(\mu\)m, $u_{e}/u_{B} \simeq 0.7$, and $L_{j,\text{min}} \simeq 8.5 \times 10^{44}$ erg s\(^{-1}\) $\simeq 0.2 L_{\text{d}}$. The gamma-ray emitting region is certainly located outside the BLR, in the region where external radiation is dominated by the dusty torus emission. The jet is predicted to be at least moderately magnetized at $r \sim 3 \times 10^{4} R_{g}$. The required minimum jet power is higher by factor $\simeq 4$ than the estimate of Meyer et al. (2011).

VLBI measurements of the jet of AO 0235+164 imply that $D/\Gamma_{j} \simeq 1.98$ and $\Gamma \beta \simeq 0.04$ (Hovatta et al. 2009; Pushkarev et al. 2009). This rather extreme solution of a very narrow and perfectly aligned jet is inconsistent with both the $L_{\text{SSC}}$ and $E_{\text{cool,obs}}$ constraints. For $D/\Gamma = 1$, the combination of $L_{\text{SSC}}$ and $E_{\text{cool,obs}}$ constraints implies that $\Gamma \theta > 0.4$.

Agudo et al. (2011b) presented a detailed discussion of the same event, and they argued that this flare was produced at the distance scale of $\sim 12$ pc, based on the VLBI imaging and cross-correlation between the gamma rays and the millimeter data. Ackermann et al. (2012) used a simple variability timescale argument to show that locating the emitting region at 12 pc would require a very high jet Lorentz factor $\Gamma \simeq 50$. Here, we find that the SSC constraint leads to a similar limit on $\Gamma$ already at $r \simeq 9$ pc. Moreover, the cooling constraint is even stronger at distances larger than $\simeq r_{\text{IR}}$, implying that energetic electrons injected at the distance of 12 pc have no chance to cool down efficiently. On the other hand, we show that if the emitting region is located at $r_{\text{IR}}$ and has a moderate Lorentz factor of $\Gamma \simeq 24$, it will be transparent to wavelengths shorter than $\simeq 1$ mm. Agudo et al. (2011b) calculated the discrete correlation function (DCF) between the gamma rays and the 1 mm light curve, showing multiple peaks in the range of delays between 0 and $-50$ days (the latter meaning that the gamma rays lead the millimeter signals). Our result is thus not in conflict with the gamma—1 mm DCF. However, our model does not allow for the possibility that the emitting region producing three-day long gamma-ray flares is transparent at 7 mm, which is the wavelength of Very Long Baseline Array observations reported by Agudo et al. (2011b). In our model, even for $\Gamma = 100$ the 7 mm photosphere would fall at a very large distance of $\simeq 90$ pc. Just like in the case of 3C 454.3 (see Section 4.1), the solution to this apparent paradox is that the variability timescale of the 7 mm radiation has to be much longer than three days. Indeed, the 7 mm light curves presented in Agudo et al. (2011b) indicate variability timescales of the order of $\simeq 80$ days. When we used this timescale to calculate the collimation ($\Gamma \theta$) and the SSA ($\lambda_{\text{SSA,obs}}$) constraints, we obtained the following solution: the $\Gamma \theta = 1$ line crosses the 7 mm photosphere at $r_{\text{app}} \simeq 6.7$ pc and $\Gamma_{j,\text{app}} \simeq 14$. This is consistent with the detection around this epoch of a superluminal radio element of apparent velocity $\beta_{\text{app}} \sim 13$ (Agudo et al. 2011b).

The close observed correspondence between the gamma-ray flares and the activity at the 7 mm wavelength does not necessarily indicate that the gamma rays should be produced co-spatially with the 7 mm core. In Appendix B, we present a simple light travel time argument according to which the gamma rays could still be produced at the distance of $\sim 1$ pc.

Our results indicate that the 12 pc scenario cannot be constrained by energetic requirements, as the required minimum jet power is only $L_{j,\text{min}} \sim 3 \times 10^{44}$ erg s\(^{-1}\) in this case. However, even a moderate jet magnetization implied by the SSC constraint puts into question the efficiency of the recombination/conical shock that is proposed by Agudo et al. (2011b) as the physical mechanism behind the 7 mm core.

4.4. 3C 279 at MJD 54880

3C 279 ($z = 0.536$, $d_{L} \simeq 3.07$ Gpc) produced a gamma-ray flare peaking at MJD 54880 that was extensively studied in Abdo.
et al. (2010b) and Hayashida et al. (2012). The gamma-ray flux doubling timescale can be estimated as $t_{var, obs} \approx 1.5$ d, and the half-peak gamma-ray luminosity is $L_{\gamma} \approx 2.6 \times 10^{47}$ erg s$^{-1}$. Following Hayashida et al. (2012), we adopt $L_d \approx 2 \times 10^{45}$ erg s$^{-1}$, $q \approx 7.5$, $L_{syn}/L_X \approx 9.2$, $M_{BH} \approx 5 \times 10^8 M_{\odot}$, and $\alpha \approx 0.7$. This implies that $r_{BLR} \approx 0.045$ pc and $r_{IR} \approx 1.1$ pc.

In Figure 4, we plot the constraints on $r$ and $\Gamma$ for this flare. The marginal solution is $r_{min} \approx 0.62$ pc and $\Gamma_{min} \approx 27$, which locates the gamma-ray emission firmly outside the BLR, and close to $r_{IR}$. The predictions for this solution are $\lambda_{SSA, obs} \approx 1.03$ mm, $u'/u'_{0} \approx 0.3$, $L_{\gamma, min} \approx 4 \times 10^{44}$ erg s$^{-1} \approx 0.2L_d$. The required jet power is roughly half of the estimate of Meyer et al. (2011).

The MOJAVE jet kinematics solution yields $D \approx 24$, $\Gamma_1 \approx 21$ (Hovatta et al. 2009), and $\Gamma_2/\Gamma_1 \approx 0.22$ (Pushkarev et al. 2009). The implied Doppler-to-Lorentz factor ratio of $D/\Gamma \approx 1.15$ is fairly close to unity. This solution is inconsistent with both the $L_{SSC}$ and $E_{cool, obs}$ constraints. For $D/\Gamma = 1$, the combination of the $L_{SSC}$ and $E_{cool, obs}$ constraints implies that $\Gamma \theta > 0.7$.

Hayashida et al. (2012) proposed two scenarios for the gamma-ray emission. One of them emphasized the connection to a 20 days scale polarization event, which implicated the location at 1–4 pc. The other was based on mid-IR spectral structure detected by Spitzer, which was interpreted as a SSA turnover. The latter implicated sub-parsec scales ($r_{BLR}$) for the main synchrotron/gamma-ray component, with an additional emitting region located at 4 pc. Our results show very clearly that location of the gamma-ray flare at $r_{BLR}$ is not consistent with the variability timescale of days, rather it would require a variability timescale of several hours. With the relatively moderate peak gamma-ray flux of 3C 279, such short timescales could not be probed with Fermi/LAT. Such timescales are essential in order to interpret the Spitzer spectral feature in terms of SSA. On the other hand, the distance of 1 pc is fully consistent with all constraints, however, shifting the emitting region to the distance of 4 pc would violate the $E_{cool, obs}$ constraint.

Dermer et al. (2014) presented a detailed model of the radiation of blazars which was applied to the 3C 279 data from Hayashida et al. (2012). They concluded that this gamma-ray flare was produced at $r \approx 0.1–0.5$ pc for $\Gamma \sim 20–30$. This is still outside the BLR, but according to Figure 4, their parameter region extends well into the $\Gamma \theta > 1$ regime. However, they assumed a very short variability timescale of $\lambda_{var, obs} \approx 10^4$ s $= 2.8$ h. We have checked the consequences of adopting $\lambda_{var} = 10^4$ s in our model. For $20 < \Gamma < 30$, we found a range of possible locations $r \approx 0.025–0.11$ pc, which are closer to the black hole than the solutions of Dermer et al. (2014). In that work, the location of the gamma-ray emitting region was constrained by calculating $u_{BLR}$ from SED modeling, and comparing it with the level $u_{BLR,0}$ expected for $r < r_{BLR}$. By noting that $u_{BLR} < u_{BLR,0}$, they concluded that $r > r_{BLR}$. However, it is difficult to provide a precise estimate of $r$ in this way, because it depends on the uncertain shape of the $u'_{BLR}(r)$ function for $r > r_{BLR}$. Because these authors allowed for higher values of the accretion disk luminosity, up to $L_d = 10^{46}$ erg s$^{-1}$, they also have higher values of $r_{BLR} \propto L_d^{1/2} \approx 0.1$ pc. Taking these differences into account, the discrepancy between their and our results does not appear to be significant.

4.5. PKS 1510-089 at MJD 54948

PKS 1510-089 ($z = 0.36$, $d_L \approx 1.92$ Gpc), the second most active blazar of the Fermi era (Nalewajko 2013), has been monitored extensively in the X-ray, optical/NIR, and radio/millimeter bands. In early 2009, it produced a series of gamma-ray flares, peaking at MJD 54917 (2009 March 27), MJD 54948 (2009 April 27), and MJD 54962 (2009 May 11) (Abdo et al. 2010a; D’Ammando et al. 2011). The first and the
last flares were accompanied by sharp optical/UV flares, but none of them had a clear X-ray counterpart. A cross-correlation analysis indicates that the optical signal could be delayed with respect to the gamma-ray signal by $\geq 13$ days, in which case the major optical flare peaking at MJD 54961 would be associated with the second gamma-ray event at MJD 54948. However, in our work we are primarily concerned with the gamma-ray emitting regions as they are when they produce a gamma-ray flare, and thus we use strictly simultaneous multiwavelength data. Therefore, we will focus on the case of MJD 54948, ignoring the optical flare that follows it. As usual, there is some ambiguity about establishing the flare parameters, and for this purpose we carefully examine the results of Abdo et al. (2010a), and compare them with our own analysis. We adopt the $\nu L_\nu$ gamma-ray luminosity of $L_\gamma \simeq 5.4 \times 10^{47}$ erg s$^{-1}$, the gamma-ray variability timescale of $t_{\text{var, obs}} \simeq 0.9$ d (Nalewajko 2013), the accretion disk luminosity of $L_d \simeq 5 \times 10^{45}$ erg s$^{-1}$ (Nalewajko et al. 2012b), the Compton dominance parameter of $L_d / L_{\text{syn}} \simeq 100$, the X-ray luminosity of $L_X \simeq 5 \times 10^{44}$ erg s$^{-1}$, the X-ray spectral index of $\alpha \simeq 0.3$, the black hole mass of $M_{\text{BH}} \simeq 4 \times 10^8 M_\odot$, the covering factors of $\xi_{\text{BLR}} = \xi_{\text{IR}} \simeq 0.1$, and the external radiation fields radii $r_{\text{BLR}} \simeq 0.07$ pc and $r_{\text{IR}} \simeq 1.8$ pc.

Our constraints for the MJD 54948 flare of PKS 1510-089 are presented in Figure 5. The SSC constraint is particularly strong in this case, since $L_{\gamma} / L_X \simeq 1000$. The marginal solution is $r_{\text{min}} \simeq 0.37$ pc at $\Gamma_{\text{min}} \simeq 26$, which is well outside the BLR. The predictions for this solution are $\lambda_{\text{SSA, obs}} \simeq 1.4$ mm, $u'_s / u'_B \simeq 12$, and $L_{\gamma, \text{min}} \simeq 2.2 \times 10^{44}$ erg s$^{-1}$, which is slightly lower than the total jet power estimate by Meyer et al. (2011). Therefore, we suggest that the jet of PKS 1510-089 is only weakly magnetized.

Abdo et al. (2010a) argued that this gamma-ray flare was produced within the BLR, as they found that the gamma-ray and optical luminosities are related roughly as $L_\gamma \propto L_{\text{opt}}$, which favors the ERC(BLR) mechanism of gamma-ray production over ERC(IR). Their SED models were calculated for $\Gamma \simeq 15$, and their SSC components peak significantly below $L_X$. This would be in strong disagreement with our results, if not for two crucial assumptions: they adopted $D/\Gamma \simeq 1.4$ and $t_{\text{var}} \simeq 0.25$ days. When these parameters are used in our model, we obtain $r_{\text{min}} \simeq 0.035$ pc at $\Gamma_{\text{min}} \simeq 12$, which is consistent with their result. We note that VLBI observations indicate that $D/\Gamma \simeq 0.8$ (Hovatta et al. 2009), so our choice of $D/\Gamma = 1$ seems to be more conservative. Abdo et al. (2010a) used the intrinsic gamma-ray opacity constraint to derive a limit on the Doppler factor $D \gtrsim 8$, which we find very conservative, and certainly weaker than the SSC constraint. They also estimated the jet power, and for this particular flare they obtained $L_j \simeq 4.8 \times 10^{45}$ erg s$^{-1}$, about 60% of which is in the magnetic form, and only $\sim 8\%$ in the radiative form. This indicates that in their model $u'_s / u'_B \simeq 0.13$, which is consistent with their low $L_{\text{SSC}}$, but this solution is likely to require $\Gamma \theta > 1$. The energetic requirements discussed by Abdo et al. (2010a) can be significantly relaxed by bringing their model closer to equipartition.

Marscher et al. (2010) presented an independent analysis of the activity of PKS 1510-089 in early 2009, including more detailed VLBI analysis and optical polarization data. The VLBI observations at 43 GHz revealed a superluminal knot of apparent velocity $22c$, which was projected to pass the stationary core at MJD $\sim 54959$, simultaneous with the major optical flare. This optical flare was accompanied by a sharp increase of the optical polarization degree, up to $\sim 37\%$, and apparently preceded by a gradual ($\sim 50$ days timescale) rotation of the optical polarization angle by $\sim 720^\circ$. They interpreted the gamma-ray activity of PKS 1510-089 as directly related to the emergence of the superluminal radio/millimeter feature, with optical polarization rotation indicating either stochastic or helical structure of the jet. This interpretation implies a $\sim 10$–20 pc distance scale.
for the gamma-ray flares, at which the ERC mechanism based on IR photons is inefficient. Instead, it was proposed that the gamma rays are produced by Comptonization of synchrotron radiation produced in slower outer jet layers (spine-sheath models, Ghisellini et al. 2005). In Appendix C.1, we show that in fact the spine-sheath model offers no advantage over the ERC model in explaining strongly beamed gamma-ray emission.

Chen et al. (2012) performed time-dependent SED modeling of the 2009 March flare of PKS 1510-089, investigating three scenarios for the gamma-ray emission: ERC(BLR), ERC(IR), and SSC. The ERC(BLR) scenario was demonstrated to require very low values of the covering factor, $\xi_{\text{BLR}} \sim 0.01$. The other two scenarios produce reasonable fits to the observed SEDs, and each scenario has its own moderate problems. The problem of localization of the gamma-ray emitting region was not directly addressed. We note that since the ERC(BLR) model should address. We note that since the ERC(BLR) model should

\[ \Gamma \]

be located at $r \lesssim r_{\text{BLR}}$, it requires $\Gamma \theta \gg 1$, especially for the adopted variability timescale of 4 d. The SSC models are difficult to localize, because their parameters are independent of the external radiation fields. However, in order to suppress the ERC component, they require a significantly lower Lorentz factor, $\Gamma \lesssim 10$, than the ERC models. We briefly discuss the constraints on SSC models in Section 6.4.

During the active state in 2009, PKS 1510-089 was detected in the very high energy (VHE) gamma-ray band, up to 300 GeV, by the H.E.S.S. observatory (H.E.S.S. Collaboration 2013). Opacity constraints due to BEL imply that the VHE emission must be produced outside the BLR (Barnacka et al. 2013), which is fully consistent with our results for the GeV emission.

4.6. PKS 1222+216 at MJD 55366

PKS 1222+216 ($z = 0.432, d_L \simeq 2.4$ Gpc) was in a very active gamma-ray state in 2010, producing major GeV flares peaking at MJD 55317 (2010 May 1) and MJD 55366 (2010 June 19) (Tanaka et al. 2011). Shortly before the latter event, the MAGIC observatory detected VHE emission (up to 400 GeV) of extremely short variability timescale, $\sim 9$ min (Alekścić et al. 2011), which proved to be very challenging to explain (Tavecchio et al. 2011, 2012; Dermer et al. 2012; Nalewajko et al. 2012a; Giannios 2013). Arguably, the only certain result concerning this VHE event is that it should be produced at the distance scale beyond $r_{\text{min,VHE}} \sim 0.5$ pc in order to avoid the absorption of the VHE photons by the BLR radiation. Here, we focus on the GeV flare peaking at MJD 55366, for which the variability timescale was estimated as $t_{\text{var,obs}} \simeq 1$ d, and the gamma-ray luminosity as $L_{\gamma} \sim 10^{48}$ erg s$^{-1}$ (Tanaka et al. 2011). Following Tavecchio et al. (2011), we adopt $L_d \sim 5 \times 10^{46}$ erg s$^{-1}$, $\xi_{\text{BLR}} \sim 0.02$, $\xi_{\text{IR}} \sim 0.2$, $q = L_{\gamma}/L_{\text{syn}} \gtrsim 100$, $L_X \sim 10^{45}$ erg s$^{-1}$, $\alpha \simeq 0.6$, $r_{\text{BLR}} \sim 0.22$ pc, and $r_{\text{IR}} \sim 5.6$ pc. There is significant uncertainty in the value of $q$, as the simultaneous Swift/UVOT spectra are dominated by the thermal component. The black hole mass was recently estimated as $M_{\text{BH}} \sim 6 \times 10^8 M_\odot$ (Farina et al. 2012).

Our constraints for the GeV flare of PKS 1222+216 are presented in Figure 6. The marginal solution is found at $r_{\text{min}} \sim 0.18$ pc and $\Gamma_{\text{min}} \simeq 17$. This location is within the BLR, and significantly closer to the black hole than the minimum location of the VHE emission. The predictions for this solution are: $\lambda_{\text{SSA,obs}} \simeq 0.76$ mm, $u'/\kappa_B \simeq 11$, and $L_{\gamma_{\text{min}}} \simeq 9.5 \times 10^{44}$ erg s$^{-1} \simeq 0.019 L_d$, which is slightly above the estimate by Meyer et al. (2011). When we increase the Compton dominance parameter to 300, we obtain $r_{\text{min}} \simeq 0.13$ pc and $\Gamma_{\text{min}} \simeq 14$. When we use a shorter variability timescale of $\sim 6$ h (Foschini et al. 2011), we obtain $r_{\text{min}} \sim 0.08$ pc and $\Gamma_{\text{min}} \simeq 23$.

The VLBI kinematic solution is rather peculiar, with $D/T_j \simeq 0.11$ (Hovatta et al. 2009), which would indicate that PKS 1222+216 is not a blazar. When we decrease our
Doppler-to-Lorentz factor ratio merely to $D/\Gamma = 0.5$, a minimum Lorentz factor of $\Gamma_{\text{min}} \simeq 52$ is required. Therefore, adopting $D/\Gamma \simeq 1$ seems to be the most reasonable option in this case.

Tavecchio et al. (2011) modeled the broadband SED of PKS 1222+216 for this particular event, considering three scenarios: a single compact emitting region for both VHE and GeV emission, separate emitting regions located outside the BLR, and separate emitting regions with the GeV radiation produced within the BLR. For the GeV emitting regions, they adopted a Lorentz factor $\Gamma = 10$ and a Doppler factor $D \simeq 20$. However, because they fixed the jet opening angle, at different distances they adopted different radii for the emitting regions, corresponding to different variability timescales. For the GeV emitting region located within the BLR, their model predicts a variability timescale of $\lesssim 10$ h, and for the region located outside the BLR, it predicts a variability timescale of $\lesssim 3$ d. When using these timescales, and a Doppler-to-Lorentz factor ratio of $D/\Gamma = 2$, our constraints are entirely consistent with the model parameters adopted by Tavecchio et al. (2011) in either scenario.

A characteristic feature of all the models of Tavecchio et al. (2011) is that the magnetic component of the jet power is strongly dominated by the particle component, which in turn is dominated by protons. However, considering only the electrons, they predict that $u'_e/u'_B \simeq 6$. Even if only a moderate fraction of the energy of electrons can power the gamma-ray emission, their model is consistent with our result that $u'_e/u'_B \lesssim 10$. We find that at moderate values of the Lorentz factor $\Gamma$ the jet can only be weakly magnetized. If the extremely rapid VHE variability is due to processes powered by relativistic magnetic reconnection (Nalewajko et al. 2012a; Giannios 2013), this requires a high jet magnetization, which is possible at the $\sim$pc scale, but only for very high Lorentz factors ($\Gamma \gtrsim 40$). Alternatively, the required regions of very high magnetization may only occupy a small fraction of the jet cross-section.

### 4.7. PKS 0208-512 at MJD 55750

PKS 0208-512 ($z = 1.003$, $d_L \simeq 6.7$ Gpc) showed several gamma-ray flares of moderate luminosity, which were studied in detail by Chatterjee et al. (2013a). What is interesting about these flares is that they show significantly variable Compton dominance parameter. Here we discuss the constraints on the parameters of one of the brightest gamma-ray flares produced by this source, peaking around MJD 55750. Preliminary results for this event were presented in Chatterjee et al. (2013b). Following that work, we adopt the following parameter values: $L_\gamma \simeq 1.7 \times 10^{47}$ erg s$^{-1}$, $t_{\text{var,obs}} \simeq 2$ d, $q = L_\gamma/L_{\text{syn}} \simeq 3.3$, $L_X \simeq 3.5 \times 10^{45}$ erg s$^{-1}$, $\alpha \simeq 0.7$, $L_\gamma \simeq 8 \times 10^{45}$ erg s$^{-1}$, $\xi \simeq 0.1$, $r_{\text{BLR}} \simeq 0.09$ pc, and $r_{\text{IR}} \simeq 2.2$ pc. While Chatterjee et al. (2013b) adopted $\Delta\Gamma/\Gamma \simeq 1.4$, here we will use $\Delta\Gamma/\Gamma = 1$ as we do for all other sources. We also adopt a black hole mass of $M_{\text{BH}} \simeq 1.6 \times 10^9 M_\odot$ (Fan & Cao 2004).

Our constraints for the gamma-ray flare in PKS 0208-512 are shown in Figure 7. The marginal solution is uncertain in this case, because the $L_{\text{SSC}}$ constraint is almost tangent to the collimation constraint, nevertheless, we adopt $r_{\text{min}} \simeq 0.2$ pc and $\Gamma_{\min} \simeq 15$. With a relatively massive black hole, we have $r_{\min} \simeq 2500 R_g$. The predictions of this solution are: $\lambda_{\text{SSA,obs}} \simeq 0.65$ mm, $u'_e/u'_B \simeq 0.26$, and $L_{\gamma,\min} \simeq 0.92 \times 10^{45}$ erg s$^{-1} \simeq 0.12L_{\nu,\delta}$. The cooling constraint, which was not considered by Chatterjee et al. (2013b), is rather strong, indicating that the jet cannot be strongly collimated, with $\Gamma \theta \gtrsim 0.3$. This means that the emitting region must be located beyond $r_{\text{BLR}}$, and possibly close to $r_{\text{IR}}$.

### 5. SENSITIVITY TO ASSUMPTIONS

There are parameters in our constraints, as in every model of blazar emission, that may not be well determined from observations. In practice, even an informed choice of the values of these parameters is to some degree an arbitrary assumption. In
In this section, we will discuss the sensitivity of our constraints to three such parameters: the Doppler-to-Lorentz factor ratio $\mathcal{D}/\Gamma$, the covering factor of external radiation sources $\xi_{\text{ext}}$ (where “ext” stands for either BLR or IR), and the observed variability timescale $t_{\text{var,obs}}$. See Figure 1 for a detailed description.

(A color version of this figure is available in the online journal.)

Figure 8. Illustration of the sensitivity of our constraints to the assumptions on the Doppler-to-Lorentz factor ratio $\mathcal{D}/\Gamma$, the external radiation source covering factor $\xi$, and the observed variability timescale $t_{\text{var,obs}}$. See Figure 1 for a detailed description.

This is a continuation of the discussion in Section 2, where we will explore the implications of varying $\mathcal{D}/\Gamma$, $\xi_{\text{ext}}$, and $t_{\text{var,obs}}$ on the constraints derived from the observed data. The reference model is calculated for $\mathcal{D}/\Gamma = 1$, $\xi_{\text{BLR}} = \xi_{\text{IR}} = 0.1$, and $M_{\text{BH}} = 10^9 M_\odot$. The second model differs from the reference model by having $\mathcal{D}/\Gamma \approx 2$. The third model differs from the reference model by having $\xi_{\text{BLR}} = \xi_{\text{IR}} = 0.2$. Finally, the fourth model differs from the reference model by having $t_{\text{var,obs}} = 12$ hr.

The effect of increasing the Doppler-to-Lorentz factor ratio $\mathcal{D}/\Gamma$ is to significantly relax the SSC constraint, allowing for much lower values of $\Gamma$. The collimation constraint is somewhat stronger, but the net effect of these two constraints is to decrease $r_{\text{min}}$. This can be understood from the fact that $\Gamma(r, \Gamma \theta) \propto (\mathcal{D}/\Gamma)^{-1/2}$ and $\Gamma(r, L_{\text{SSC}}) \propto (\mathcal{D}/\Gamma)^{-1}$ (see Equations (1) and (5)). The cooling constraint is affected only slightly, since $\Gamma(r, E_{\text{cool,obs}}) \propto (\mathcal{D}/\Gamma)^{-1/4}$ (see Equation (9)).

The relation between the “equipartition” parameter $u'_j/u'_B$ and the SSC constraint is independent of $\mathcal{D}/\Gamma$ (see Equation (21)), therefore lines of constant $L_{\text{SSC}}$ correspond to the same values of $u'_j/u'_B$ as in the reference model. The dependence of the intrinsic opacity constraint $\Gamma(E_{\text{max,obs}})$ on $\mathcal{D}/\Gamma$ (see Equation (14)) is the same as that of the SSC constraint. Although the gradients of $E_{\text{max,obs}}$ in the ($r, \Gamma$) space are large, the value of $E_{\text{max,obs}}$ for the marginal solution decreases only slightly. The minimum jet power is also significantly relaxed, especially in the region dominated by the radiation energy density. However, in the more relevant region dominated by the magnetic energy density, $\Gamma(r, L_{\text{jet,\min}}) \propto (\mathcal{D}/\Gamma)^{-2/3}$ (see Equation (25)), and the lines...
of constant $L_{1,\text{min}}$ are aligned roughly parallel to the lines of constant $L_{\text{SSC}}$. Because of steep gradients of $L_{1,\text{min}}$ in the ($r$, $\Gamma$) space, its value is very sensitive to the exact location within the allowed region. Finally, the dependence of the SSA constraint $\Gamma(r, v_{\text{SSA}})$ on $D/\Gamma$ (see Equation (18)) is the same as that of the SSC constraint, and the gradients of $v_{\text{SSA,obs}}$ in the ($r$, $\Gamma$) space are very small. Therefore, the predicted SSA characteristic frequency for the marginal solution will be only weakly affected. We conclude that while the allowed parameter space region for higher $D/\Gamma$ is significantly extended toward lower values of $r$ and $\Gamma$, most parameter values corresponding to the marginal solution ($r_{\text{min}}, \Gamma_{\text{min}}$) are not very sensitive to the choice of $D/\Gamma$.

The effect of increasing the covering factor $\xi \equiv \xi_{\text{BLR}} = \xi_{\text{IR}}$ is relatively minor. Our constraints scale with $\xi$ as: $\Gamma(r, \Gamma \theta) \propto \xi^0$, $\Gamma(r, L_{\text{SSC}}) \propto \xi^{-1/8}$, $\Gamma(r, E_{\text{cool}}) \propto \xi^{-1/2}$, $\Gamma(r, v_{\text{SSA,obs}}) \propto \xi^{1/8}$, $\Gamma(E_{\text{max,obs}}) \propto \xi^0$, $\Gamma(L_{\text{J,\rho,\min}}) \propto \xi^0$, and $\Gamma(r, L_{1,\text{B,\min}}) \propto \xi^{-1/6}$.

The cooling constraint is moderately relaxed, extending the allowed parameter space region toward higher values of $r$. Other scalings are very weak, and therefore we conclude that the choice of $\xi$ is not critical in our analysis.

The effect of decreasing the observed variability timescale $t_{\text{var,obs}}$ is quite significant. Our constraints scale with $t_{\text{var,obs}}$ as: $\Gamma(r, \Gamma \theta) \propto t_{\text{var,obs}}^{-1/2}$, $\Gamma(r, L_{\text{SSC}}) \propto t_{\text{var,obs}}^{-1/2}$, $\Gamma(r, E_{\text{cool}}) \propto t_{\text{var,obs}}^{-1/2}$, $\Gamma(r, v_{\text{SSA,obs}}) \propto t_{\text{var,obs}}^{-1/2}$, $\Gamma(E_{\text{max,obs}}) \propto t_{\text{var,obs}}^{-1/2}$, $\Gamma(L_{\text{J,\rho,\min}}) \propto t_{\text{var,obs}}^0$, and $\Gamma(r, L_{1,\text{B,\min}}) \propto t_{\text{var,obs}}^{-1/3}$. The allowed parameter space region is shifted toward smaller values of $r$ due to relaxed collimation constraint and tighter cooling constraint, and the SSA is noticeably stronger, but other parameters are not strongly affected.

In summary, the uncertainty in the Doppler-to-Lorentz factor ratio is the most significant unknown in our model, but the general conclusions that we draw for each case analyzed in Section 4 are securely robust.

6. DISCUSSION

We have demonstrated that it is possible to significantly constrain the parameter space distance from the central SMBH $r$ and Lorentz factor $\Gamma$ of emitting regions responsible for bright gamma-ray flares of luminous blazars in the framework of the ERC mechanism, using five direct observables: gamma-ray luminosity $L_{\gamma}$, gamma-ray variability timescale $t_{\text{var,obs}}$, synchrotron luminosity $L_{\text{syn}}$, X-ray luminosity $L_{X}$, and accretion disk luminosity $L_{\text{d}}$. A combination of the collimation constraint ($\Gamma \theta \lesssim 1$), the SSC constraint ($L_{\text{SSC}} \lesssim L_{X}$), and the cooling constraint ($E_{\text{cool,obs}} \lesssim 100$ MeV) defines a parameter space region such that for each value of $\Gamma > \Gamma_{\text{min}}$, the range of $r$ is limited to $\sim 2–10$. This is a significant improvement over previous studies, which are typically limited to deciding between the BLR and IR regions, with $r_{\text{IR}}/r_{\text{BLR}} \sim 30$ (e.g., Sikora et al. 2009; Dotson et al. 2012; Brown 2013). Moreover, we evaluate the effect on our results of the most uncertain parameters like Doppler-to-Lorentz factor ratio $D/\Gamma$, or covering factor $\xi$ of external radiation sources. Further progress is possible with improved multiwavelength observations of blazars, if they can be used to securely pinpoint the SSA frequency $v_{\text{SSA,obs}}$.

6.1. Collimation Parameter

While we have imposed an upper limit on the collimation parameter $\Gamma \theta \lesssim 1$, the SSC and cooling constraints provide a firm lower limit. In some analyzed cases (Figure 4), this limit is as strong as $\Gamma \theta \gtrsim 0.7$. In other cases (Figure 6), values of $\Gamma \theta \lesssim 0.1$ can be obtained only for Lorentz factors $\Gamma \gtrsim 25$. Such tight lower limits may be in conflict with VLBI radio observations that imply significantly tighter upper limits, with $\Gamma \theta \lesssim 0.3$ (Pushkarev et al. 2009; Clausen-Brown et al. 2013). However, these radio observations probe the jet geometry at many parsec scales, and it is not clear whether these results are relevant for parsec-scale jets. Also, the Lorentz factor $\Gamma$ of the emitting region may be larger than the jet Lorentz factor $\Gamma_{J}$. In any case, we can securely conclude that very narrow opening angles of the gamma-ray emitting regions are excluded by the SSC and cooling constraints. This makes any model of energy dissipation in jets which operates on a small fraction of the jet cross-section, in particular reconfined shocks leading to very narrow nozzles (e.g., Bromberg & Levinson 2009), inconsistent with the ERC scenario. This also challenges models of strongly structured jets, e.g., the spine-sheath models (Ghisellini et al. 2005), or models involving strongly localized dissipation sites, e.g., minijets (Giannios et al. 2009), unless they can be distributed uniformly across a large fraction of the jet cross-section. While these models can still explain the most extreme modes of blazar variability, in particular the sub-hour VHE gamma-ray flares (Aleksić et al. 2011), they may not be responsible for the bulk of the gamma-ray emission of blazars.

6.2. Marginal Solutions

The intersection between the collimation constraint and the SSC constraint defines the marginal solution ($r_{\text{min}}, \Gamma_{\text{min}}$), which sets firm lower limits on both $r$ and $\Gamma$. One can derive the marginal solution from Equations (1) and (5):

$$r_{\text{min}} \simeq \frac{c t_{\text{var,obs}}}{(1+z)} \left[ \frac{3}{4} \left( \frac{g_{\text{SSC}}}{g_{\text{ERC}}} \right) \left( \frac{L_{\text{syn}}}{L_X} \right) \left( \frac{L_{\gamma}}{\xi(r_{\text{min}}) L_d} \right) \right]^{1/2} \times \left( \frac{D}{\Gamma} \right)^{-2},$$

(26)

$$\Gamma_{\text{min}} \simeq \left[ \frac{3}{4} \left( \frac{g_{\text{SSC}}}{g_{\text{ERC}}} \right) \left( \frac{L_{\text{syn}}}{L_X} \right) \left( \frac{L_{\gamma}}{\xi(r_{\text{min}}) L_d} \right) \right]^{1/4} \times \left( \frac{D}{\Gamma} \right)^{-3/2}.$$  

(27)

Because of the dependence of $\xi$ on $r$, Equation (26) is not explicit, but the solutions discussed below are calculated self-consistently. One can see that the minimum distance scale $r_{\text{min}}$ is proportional to the observed variability timescale $t_{\text{var,obs}}$. Both $r_{\text{min}}$ and $\Gamma_{\text{min}}$ depend strongly on the Doppler-to-Lorentz ratio, and they are weak functions of the broadband SED shape. The marginal solutions for the cases analyzed in Section 4 are listed in Table 1. Even with this very small sample, we can point to some general trends and differences. The minimum distance ranges between $0.16 \lesssim r_{\text{min}} [\text{pc}] \lesssim 0.65$. In terms of gravitational radii, the range is $2500 \lesssim r_{\text{min}}/R_\odot \lesssim 33,000$, which is much wider than the spread of black hole mass estimates for the six analyzed blazars—$4 \times 10^8 \lesssim M_{\text{BH}}/M_\odot \lesssim 1.6 \times 10^9$. In terms of the BLR radii, the range is $0.62 \lesssim r_{\text{min}}/r_{\text{BLR}} \lesssim 14$. Interestingly, the range of absolute values of $r_{\text{min}}$ is much narrower than the ranges of relative values of $r_{\text{min}}/R_\odot$ and $r_{\text{min}}/r_{\text{BLR}}$. Flares with relatively large $r_{\text{min}}$ happen to be both long and faint. The minimum Lorentz factor ranges between $15 \lesssim \Gamma_{\text{min}} \lesssim 30$. It does not show an obvious trend with the gamma-ray luminosity $L_{\gamma}$ or with the timescale $t_{\text{var,obs}}$. 

14
in conflict with the equipartition condition and provides a lower limit on the total electron energy density closely probes the high-energy end of the electron population, the magnetic fields for the marginal solution is given by (cf. Equation (21)):

$$u'_g \lesssim \frac{L_g}{\gamma^{2/3} \lambda_{SSC}^2}.$$  

One can see that it depends only on the broadband SED shape. From Table 1, we find that it ranges between 0.26 ≤ \(u'_g/u'_B\) < 12. Values lower by about order of magnitude are possible sometimes imposed on blazar models (e.g., Böttcher et al. 2009; Agudo et al. 2011b; Hayashida et al. 2012; Dermer et al. 2014). This also indicates that the gamma-ray radiation density \(L'_g\) from cold, warm electrons and protons, the total jet powers \(L_{j,min}\) (and higher jet magnetization). For five blazars (excluding PKS 0208-512), we compare \(L_{j,min}\) with the estimates \(L_{j,11}\) of total jet power by Meyer et al. (2011). We find that in many cases our lower limits significantly exceed \(L_{j,11}\), with 0.44 ≤ \(L_{j,min}/L_{j,11}\) ≤ 8.5. Since our estimates do not take into account the contributions from cold/warm electrons and protons, the total jet powers required to power the observed gamma-ray flares may be comparable to, or even exceed, the accretion disk luminosity (in agreement with Ghisellini et al. 2009), and they are certain to be significantly higher than the estimates of Meyer et al. (2011). This indicates that the total jet powers in blazars are strongly variable, and that the values estimated from energetics of the brightest gamma-ray flares (this work) can exceed by more than order of magnitude higher the average values inferred from the low-frequency (300 MHz) radio luminosity (Meyer et al. 2011).

The SSA wavelength for the marginal solutions ranges between 0.125 ≤ \(\lambda_{SSA,obs}\) [mm] ≤ 1.4. For other allowed solutions \(\lambda_{SSA}\) will be somewhat larger. The SSA threshold appears to be better correlated with the gamma-ray luminosity \(L'_g\) than with the observed variability timescale \(\tau_{var}\). For five events with marginal \(\lambda_{SSA,obs} > 0.5\) mm, a fairly close correlation between the gamma rays and the mm data can be expected (Sikora et al. 2008). However, for the bright flares of 3C 454.3, where marginal \(\lambda_{SSA,obs} < 0.2\) mm, we expect that the millimeter signal should be significantly delayed with respect to the gamma-ray signal. The gamma-ray emitting regions for the analyzed events cannot be transparent at the 7 mm wavelength. 

The energy density ratio of the gamma-ray radiation to the magnetic fields for the marginal solution is given by (cf. Equation (21)):

$$\frac{u'_g}{u'_B} \lesssim \frac{L_g}{\gamma^{2/3} \lambda_{SSC}^2}.$$  

One can see that it depends primarily on the gamma-ray luminosity, relatively weakly on the Doppler-to-Lorentz ratio, and to some degree also on the broadband SED shape. Our estimates of the minimum jet power for the analyzed cases (Table 1) range between 2.2 × 10^{44} ≤ \(L_{j,min}\) [erg s^{-1}] ≤ 1.7 × 10^{46}, which is significantly narrower than the range of apparent gamma-ray luminosities 1.7 × 10^{47} ≤ \(L'_g\) [erg s^{-1}] ≤ 4.7 × 10^{49}. In terms of the accretion disk luminosity, we find 0.019 ≤ \(L_{j,min}/L_d\) ≤ 0.25. There is a trend for this ratio to be higher for lower Compton dominance \(q\) (and higher jet magnetization). For five blazars (excluding PKS 0208-512), we compare \(L_{j,min}\) with the estimates \(L_{j,11}\) of total jet power by Meyer et al. (2011). We find that in many cases our lower limits significantly exceed \(L_{j,11}\), with 0.44 ≤ \(L_{j,min}/L_{j,11}\) ≤ 8.5. Since our estimates do not take into account the contributions from cold/warm electrons and protons, the total jet powers required to power the observed gamma-ray flares may be comparable to, or even exceed, the accretion disk luminosity (in agreement with Ghisellini et al. 2009), and they are certain to be significantly higher than the estimates of Meyer et al. (2011). This indicates that the total jet powers in blazars are strongly variable, and that the values estimated from energetics of the brightest gamma-ray flares (this work) can exceed by more than order of magnitude higher the average values inferred from the low-frequency (300 MHz) radio luminosity (Meyer et al. 2011).
Because of the weak dependence of \( \lambda_{\text{SSA,obs}} \) on either \( r \) or \( \Gamma \), \( \text{SSA can potentially provide very strong additional constraints on the parameters of gamma-ray emitting regions in blazars.} \)

The intrinsic gamma-ray opacity does not provide a significant constraint in the analyzed cases, with \( \Gamma (E_{\text{max,obs}} = 100 \, \text{GeV}) \lesssim 10 \). In every analyzed case, the SSC constraint gives a stronger upper limit on \( \Gamma \), as first noted by Ackermann et al. (2010).

### 6.3. Maximum Distance Scale

For a given value of the Lorentz factor \( \Gamma \), the maximum distance \( r_{\text{max}}(\Gamma) \) is determined either by the SSC constraint, or by the cooling constraint. Eventually, at some \( \Gamma_{\text{max}} \) there is a solution where the cooling constraint crosses the collimation constraint, which gives an absolute upper limit \( r_{\text{max}}(\Gamma_{\text{max}}) \).

However, the values of \( \Gamma_{\text{max}} \) can be extremely high (\( \Gamma_{\text{max}} \gg 50 \)), especially for sources with high accretion disk luminosity \( L_d \) (3C 454.3 and PKS 1222+216), for which the cooling constraint is relatively weak. Therefore, the effective maximum distance scale depends on how high values of \( \Gamma \) one would accept.\(^{10} \)

For a rather high \( \Gamma_{\text{max}} = 50 \) (\( \Gamma_{\text{max}} \approx 46 \) in the case of 3C 279), we obtain \( 0.8 \lesssim r_{\text{max}} \lesssim 10.7 \) (see Table 1). In terms of the IR radii, the range is \( 0.12 \lesssim r_{\text{max}} / r_{\text{IR}} \lesssim 2.1 \). The ratio of maximum to minimum distances is in the range \( 2.8 \lesssim r_{\text{max}} / r_{\text{min}} \lesssim 59 \).

If the cooling constraint can be relaxed due to the swinging motion of the emitting region, we can still place significant limits on the far-dissipation scenario by using solely the SSC constraint. In most analyzed cases, locating the gamma-ray emitting regions at \( r \approx 10 \, \text{pc} \) would require \( \Gamma > 50 \).

### 6.4. Limits to the ERC Model

In Section 4.3, we discussed the tension between the constraints imposed by the ERC model and the far dissipation \((\approx 10 \, \text{pc})\) scenarios motivated by the observed gamma-ray/millimeter-radio connection. We showed that the SSC constraint requires very high Lorentz factors, \( \Gamma > 50 \), in order for gamma-ray flares with a variability timescale of \( \approx 1 \, \text{day} \) to be produced at the distance scale of \( \approx 10 \, \text{pc} \).

These solutions are also characterized by inefficient electron cooling \( (E_{\text{cool,obs}} > 100 \, \text{MeV}) \), which would result in strongly asymmetric gamma-ray light curves with long flux-decay timescales, unless there are fast variations in the local Doppler factor. Alternative sources of external radiation at large distance scales were proposed as a way around these problems. In Appendix C, we discuss two such ideas—spine-sheath models (e.g., Marscher et al. 2010), and extended BLRs (León-Tavares et al. 2011).

While far less popular than the ERC model, the SSC model is still being considered when modeling FSRQ blazars (e.g., Finke & Dermer 2010; Zacharias & Schlickeiser 2012; Chen et al. 2012). It was suggested that the SSC model is most relevant for FSRQs with relatively low kinetic jet power (Meyer et al. 2012). Such models can be characterized by two conditions: \( L_{\text{SSC}} = L_y \) and \( L_{\text{ERC}} < L_{\text{SSC}} \) (one should note that in this case \( L_{\text{ERC}} \) may be suppressed, being strongly in the Klein–Nishina regime due to higher electron energies). With minor modifications, we can use our constraints to identify the parameter space region where these conditions can be satisfied. Our SSC constraint (Equation (5)) is more generally a constraint on the luminosity ratio \( L_{\text{SSC}} / L_{\text{ERC}} \), which increases systematically with decreasing \( \Gamma \). One can extrapolate from the lines of constant \( L_{\text{SSC}} \) shown on Figures 1–7 \((L_{\text{SSC}} / L_{\text{ERC}} = L_{\text{SSC}} / L_y \ll 1)\) to the case of \( L_{\text{SSC}} / L_{\text{ERC}} = L_y / L_{\text{ERC}} > 1 \) corresponding to moderate and low Lorentz factors, \( \Gamma \lesssim 10 \).

The parameter space of the SSC model is clearly separated from the parameter space of the ERC model. At distances of \( \approx 10 \, \text{pc} \), SSC model may be favored over the ERC model, the latter requiring extreme values of \( \Gamma \).

There are additional very strong constraints on the SSC model from the observed broad-band SEDs of luminous blazars. While being very successful in explaining the emission of low-luminosity HBL blazars, SSC models can have serious difficulties in matching the observed SEDs of FSRQs (e.g., Joshi et al. 2012). In order to match the characteristic frequencies of the two main spectral components, SSC models typically require very low magnetic field strength and high average electron random Lorentz factor, which independently suggests a particle-dominated emitting region. A more detailed analysis of the spectral constraints on the SSC model is beyond the scope of this work.

### 7. CONCLUSIONS

We investigated several constraints on the location \( r \) and the Lorentz factor \( \Gamma \) of gamma-ray emitting regions in the jets of luminous blazars, assuming that the gamma-ray emission is produced by the ERC mechanism. In Section 2, we defined four such constraints, based on: collimation parameter \( \Gamma \beta \), SSC luminosity \( L_{\text{SSC}} \), observed photon energy corresponding to efficient cooling threshold \( E_{\text{cool,obs}} \), and maximum photon energy \( E_{\text{max,obs}} \) due to intrinsic gamma-ray opacity. In Section 3, we also considered specific predictions for given \((r, \Gamma) \)—SSA frequency \( \nu_{\text{SSA,obs}} \), and minimum jet power \( L_j \) including only contributions from high-energy electrons and magnetic field. In practical application, these constraints require five direct observables—gamma-ray luminosity \( L_y \), gamma-ray variability timescale \( \tau_{\text{var,obs}} \), synchrotron luminosity \( L_{\text{syn}} \) (or Compton dominance parameter \( q = L_y / L_{\text{syn}} \)), X-ray luminosity \( L_X \), and accretion disk luminosity \( L_d \)—and a small number of assumptions: Doppler-to-Lorentz factor ratio \( D / \Gamma \), and covering factors of external radiation sources \( \xi_{\text{BLR}}, \xi_{\text{IR}} \). The sensitivity of the constraints to the assumptions was evaluated in Section 5. In Section 4, we applied these constraints to several well-known gamma-ray flares for which extensive multiband data are available. For each studied case, we plot the parameter space \((r, \Gamma)\) to illustrate our results (Figures 1–7).
We find that the most useful constraints on $r$ and $\Gamma$ can be derived from the combination of three conditions: $\Gamma \theta \lesssim 1$, $L_{\text{SSC}} \lesssim L_X$, and $E_{\text{cool,obs}} \lesssim 100$ MeV. They define a characteristic region in the parameter space anchored at the marginal solution ($r_{\text{min}}, \Gamma_{\text{min}}$). In the analyzed cases, we found that $0.16 \lesssim r_{\text{min}}$ [pc] $\lesssim 0.65$ and $15 \lesssim \Gamma_{\text{min}} \lesssim 50$. Larger distances are possible only for higher Lorentz factors, but eventually they are limited by the cooling constraint. The size of the allowed parameter space region is particularly small for sources with low accretion disk luminosity $L_d$.

Our constraints challenge the far-dissipation scenarios inspired by the observed gamma-ray/millimeter connection. As we show in Appendix B, light travel time effects can easily explain the temporal coincidence between gamma-ray flares and the radio/millimeter activity, even when the gamma-ray emitting region is located far upstream from the radio/millimeter core. As we show in Appendix C.1, external radiation fields cannot be substituted at large distances by synchrotron radiation from a slower jet sheath. However, as we discuss in Appendix C.2, a scenario involving an extended BLR (León-Tavares et al. 2011) may provide an alternative source of external radiation.

The upper limit on $L_{\text{SSC}}$ can be translated into a lower limit on the collimation parameter, $\Gamma \theta \gtrsim 0.1$–0.7, which means that dissipation cannot be limited to very compact jet substructures like reconnection nozzles, spines, minijets, etc. Our results support the idea that pc-scale blazar jets should be close to energy equipartition between the particle and magnetic components.

The intrinsic opacity constraint on the Lorentz factor is always weaker than the SSC constraint. The SSA constraint can significantly improve the determination of the parameters of gamma-ray emitting regions, if sufficient multiwavelength data can be collected, possibly resolving the degeneracy in the values of the Doppler and covering factors.

We thank the anonymous referee for valuable comments on the manuscript, and Alan Marscher for discussions. **APPENDIX A**

**EXTERNAL RADIATION DISTRIBUTION**

In this work, we adopt a specific geometry of the BLR and the dusty torus where external radiation fields are produced (see Figure 9). Both regions are assumed to be symmetric with respect to the jet axis, and they span a distance range (measured from the SMBH) of $r_{\text{ext,min}} \leq r_{\text{ext}} \leq r_{\text{ext,max}}$ and an equatorial angle range (measured from the accretion disk plane, perpendicular to the jet axis) of $-\alpha_{\text{ext,max}} \leq \alpha_{\text{ext}} \leq \alpha_{\text{ext,max}}$. The fraction of accretion disk radiation reprocessed over unit radius $d\alpha_{\text{ext}}$ is assumed to scale as $\xi(r_{\text{ext}}) \propto r_{\text{ext}}^{-1}$, and it is normalized so that the effective covering factor is $\xi_{\text{ext}} = \int_{r_{\text{ext,min}}}^{r_{\text{ext,max}}} \xi(r) \, d\alpha_{\text{ext}}$.

![Figure 9](https://example.com/image.png)

Figure 9. Geometry of the external radiation emitting region adopted in this work for both the broad-line region and the dusty torus. See Appendix A for details.

(A color version of this figure is available in the online journal.)

This simple model has only four significant parameters: $r_{\text{ext,min}}, \alpha_{\text{ext,max}}, \xi_{\text{ext}}$, and $\beta_{\text{ext}}$. Two of them can be robustly constrained from standard observational arguments—$r_{\text{ext,min}} = r_{\text{BLR(IR)}} \propto L^{1/2}$, and $\xi_{\text{ext}} = \xi_{\text{BLR(IR)}} \sim 0.1$ (specific values are provided for each case analyzed in Section 4). The parameters $\alpha_{\text{ext,max}}$ and $\beta_{\text{ext}}$ determine the scale height and the radial stratification of the external radiation emitting region, respectively. These parameters are poorly understood, but the results are sensitive mainly to the former. In this work, we assume that $\alpha_{\text{ext,max}} = 45^\circ$ and $\beta_{\text{ext}} = 4$. In the case of planar geometry, with $\alpha_{\text{ext,max}} \lesssim 10^\circ$ (Tavecchio & Ghisellini 2012), we would need to introduce an additional geometrical correction factor of the order of $\sim 0.1$–0.2 (Sikora et al. 2013).

We now calculate the energy density of external radiation fields in the emitting region co-moving frame at the jet axis at distance $r$ from the SMBH (point A). Consider an infinitesimal volume element $dV = dA \, d\alpha_{\text{ext}}$. The energy density of direct accretion disk radiation at point B is $u_{\text{d}}(r_{\text{ext}}) \simeq L_d/(4\pi r_{\text{ext}}^2)$ (point B). The luminosity of the radiation reprocessed by this volume element is $d\mathcal{L}_{\text{ext}} = \xi(r_{\text{ext}})u_{\text{d}}(r_{\text{ext}}) \, dA$. Its contribution to the co-moving energy density of external radiation at point A is $du'_{\text{ext}} = D_{\text{ext}}^2 \mathcal{L}_{\text{ext}}/(4\pi r_{\text{ext}}^2)$, where $D_{\text{ext}} = \Gamma(1 + \beta \cos \theta_{\text{ext}})$ is the Doppler factor of point B with respect to point A in the emitting region co-moving frame, $\tan \theta_{\text{ext}} = r_{\text{ext}} \sin \alpha_{\text{ext}}(r_{\text{ext}} \sin \alpha_{\text{ext}} - r)$, and $\theta_{\text{ext}} = \Gamma(1 + \beta \cos \theta_{\text{ext}})$.

11 For $\beta_{\text{ext}} \gg 1$, the value of $r_{\text{ext,max}}$ is of minor importance. Here we adopt $r_{\text{ext,max}} = 30 \, r_{\text{ext,min}}$. 
Finally, we identify simple analytical forms that can reasonably well approximate the numerically calculated functions $u'_{\text{ext}}(r)$ and $E_{\text{ext}, \text{peak}}(r)$. These forms are presented in Equations (4) and (6) in Section 2.2.

### APPENDIX B  
#### GAMMA-RAY/MILLIMETER CONNECTION

As we discussed in Section 4.3, the observational connection between many major gamma-ray flares and radio/millimeter activity of blazar jets has been used to argue that gamma-ray flares should be produced close to the location of radio/millimeter cores, at the distance scale $r_{\text{core}} \approx 10$ pc. Here, we use a very simple light travel time argument to demonstrate that this inference is not valid. The radio/millimeter activity typically consists of a $t_{\text{mm}} \approx 100$ days long radio/millimeter outburst and a supraluminal radio/millimeter knot propagating downstream from the core, whose estimated moment of crossing the radio core coincides with the radio/millimeter outburst. We approximate the supraluminal knot by a shell of fixed thickness $l_{\text{mm}}$ propagating with the Lorentz factor $\Gamma_{\text{mm}} = (1 - \beta_{\text{mm}}^2)^{-1/2} \approx 20$. We relate the shell thickness to the radio/millimeter outburst duration by $l_{\text{mm}} \approx \beta_{\text{mm}}^{-1} \Gamma_{\text{mm}}^{-1} \approx 0.084$ pc. We choose the time coordinate such that at $t = 0$ the front of the shell crosses the location of the radio/millimeter core, and thus the tail of the shell crosses the radio/millimeter core at $t = t_{\text{mm}}$ (see Figure 10). A gamma-ray flare is “observed” (gamma-ray photons cross the radio/millimeter core) at $t_{\gamma, \text{obs}} = k t_{\text{mm}}$, where $0 < k \lesssim 1$. However, we assume that the gamma-ray flare was produced at $r_f \approx 1$ pc. Thus, the gamma-ray photons were emitted at $t_{\gamma, \text{em}} = t_{\gamma, \text{obs}} - (r_{\text{core}} - r_f)/c$. At that time, the front of the shell was located at $r_2 \approx r_f + (r_{\text{core}} - r_f)/(2l_{\text{mm}}^2) + k l_{\text{mm}}$, and its tail at $r_1 = r_f - l_{\text{mm}}$. We can see that $r_2 > r_f$, while the criterion for $r_1 < r_f$, which means that the gamma-ray emission site was within the shell, is:

$$k < 1 - \frac{r_{\text{core}} - r_f}{2l_{\text{mm}}^2 \beta_{\text{mm}}^{-1} c t_{\text{mm}}}.$$

As long as $(r_{\text{core}} - r_f) \ll 2l_{\text{mm}}^2 \beta_{\text{mm}}^{-1} c t_{\text{mm}}$, it is easy to have the gamma-ray flare produced within the shell. For our fiducial parameters, this criterion is $k < 0.87$. One can see that temporal coincidence, and even causality, between the gamma-ray flares and the radio/millimeter outburst does not imply that they are produced co-spatially.

### APPENDIX C  
#### FAR-DISSIPATION SOLUTIONS

We showed that two of our constraints, the $L_{\text{SSC}}$ constraint and the $E_{\text{cool,obs}}$ constraint, are likely violated at large distance scales. Here, we consider formal requirements to satisfy these constraints for an arbitrary $(r_0, \Gamma_0)$. From the $L_{\text{SSC}}$ constraint (Equation (5)), we find the following condition:

$$u'_{\text{ext}} > 0.09 \text{ erg cm}^{-3} \times (1 + z)^2 \left( \frac{D}{\Gamma} \right)^{-8} \left( \frac{\Gamma_0}{20} \right)^{-6} \times \left( \frac{t_{\text{var,obs}}}{1 \text{ d}} \right)^2 \left( \frac{L_{\gamma,48} L_{\text{syn},47}}{L_{X,46}} \right).$$

(C1)

From the $E_{\text{cool,obs}}$ constraint (Equation (9)), we find:

$$u'_{\text{ext}} > 0.11 \text{ erg cm}^{-3} \times (1 + z)^{1/2} \left( \frac{D}{\Gamma} \right)^{-1/2} \times \left( \frac{t_{\text{var,obs}}}{10 \text{ eV}} \right) \left( \frac{E_{\text{ext}}}{1 \text{ d}} \right)^{1/2}.$$

(C2)

Both the $L_{\text{SSC}}$ and $E_{\text{cool,obs}}$ constraints can be satisfied for a sufficiently high external radiation density. For comparison, typical co-moving energy densities of BLR and IR components are of the order of $u'_{\text{BLR}} \sim 15 \text{ erg cm}^{-3} (\xi_{\text{BLR}}/0.1)(\Gamma_0/20)^2$ for $r \lesssim 0.1$ pc and $u'_{\text{IR}} \sim 0.024 \text{ erg cm}^{-3} (\xi_{\text{IR}}/0.1)(\Gamma_0/20)^2$ for $r \lesssim 2.5$ pc, respectively. The proposers of the far-dissipation scenarios have recognized the requirement for additional sources of external radiation. In the following, we will evaluate two particular scenarios: a spine-sheath model (e.g., Marscher et al. 2010), and an extended BLR (León-Tavares et al. 2011).

#### C.1. Spine-sheath Models

In the spine-sheath model, the jet consists of a highly relativistic spine surrounded by a mildly relativistic sheath (Ghisellini et al. 2005). Let us denote the spine co-moving luminosity by $L_{\gamma, \text{sp}}$ and the sheath co-moving luminosity by $L_{\gamma, \text{sh}}$. Consider that the gamma-ray flares are produced in the spine by Comptonization of synchrotron radiation originating from the spine, and that the synchrotron radiation from the spine region contributes significantly to the observed optical/IR emission. The required energy density of the sheath radiation in $O'$ is $u'_{\text{sh}} \approx 0.1 \text{ erg cm}^{-3}$. If the sheath propagates with Lorentz factor $\Gamma_{\text{sh}}$ in the external frame, the radiation energy density in $O''$ is $u''_{\text{sh}} \approx u'_{\text{sh}}/(4\Gamma_{\text{sh}}^2)$, where $\Gamma_{\text{sh}} = \Gamma_{\text{sh}}(1 - \beta_{\text{sh}}\beta) \approx \Gamma/2\Gamma_{\text{sh}}$ is the relative Lorentz factor of $O''$ in $O'$ (the approximation is done in the limit where $1 \ll \Gamma_{\text{sh}} \ll \Gamma$). We can calculate the apparent luminosity of the sheath radiation for an external observer aligned with the jet spine as $L_{\text{sh,obs}} = 4\pi c \Gamma_{\text{sh}}^2 R_{\text{sh}}^2 u''_{\text{sh}}$, where $R_{\text{sh}} \approx \theta_{\text{sh}} r$ is the sheath radius parameterized by the sheath opening angle $\theta_{\text{sh}}$. Putting this all together, we find:
we adopt $\xi_{\text{int}} \sim 10^{-3}$ in order to have $L_{\text{BLR}}^* \simeq \xi_{\text{int}} L_{\text{syn}} \sim 10^{44} \text{ erg s}^{-1}$:

$$u_{\text{BLR}}^* \simeq \frac{\xi_{\text{int}} \Gamma^4 L_{\text{syn}}}{3 \pi c (r_{\text{BLR}}^* - r_{\text{syn}})^2} \simeq 0.24 \text{ erg cm}^{-3} \times \sqrt{\frac{L_{\text{BLR}}^*}{5 \text{ pc}}} \simeq 0.24 \text{ erg cm}^{-3}. \quad (C5)$$

In principle, this mechanism can provide enough of external radiation density to satisfy the $L_{\text{SSC}}$ and $L_{\text{cool,obs}}$. However, we suggest that more observational support for the existence of such emission lines is necessary.
