We have measured the polarizations of $J/\psi$ and $\psi(2S)$ mesons as functions of their transverse momentum $p_T$ when they are produced promptly in the rapidity range $|y| < 0.6$ with $p_T \geq 5$ GeV/c. The analysis is performed using a data sample with an integrated luminosity of about $800 \text{ pb}^{-1}$ collected by the CDF II detector. For both vector mesons, we find that the polarizations become increasingly longitudinal as $p_T$ increases from 5 to 30 GeV/c. These results are compared to the predictions of nonrelativistic quantum chromodynamics and other contemporary models. The effective polarizations of $J/\psi$ and $\psi(2S)$ mesons from $B$-hadron decays are also reported.

PACS numbers: 13.88.+e, 13.20.Gd, 14.40.Lb
An effective field theory, nonrelativistic quantum chromodynamics (NRQCD) [1], provides a rigorous formalism for calculating the production rates of charmonium ($c\bar{c}$) states. NRQCD explains the direct production cross sections for $J/\psi$ and $\psi(2S)$ mesons observed at the Tevatron [2, 3] and predicts their increasingly transverse polarizations as $p_T$ increases, where $p_T$ is the meson’s momentum component perpendicular to the colliding beam direction [4]. The first polarization measurements at the Tevatron [5] did not show such a trend. This Letter reports on $J/\psi$ and $\psi(2S)$ polarization measurements with a larger data sample than previously available. This allows the extension of the measurement to a higher $p_T$ region and makes a more stringent test of the NRQCD prediction.

The NRQCD cross section calculation for $c\bar{c}$ production separates the long-distance nonperturbative contributions from the short-distance perturbative behavior. The former is treated as an expansion of the matrix elements in powers of the nonrelativistic charm-quark velocity. This expansion can be computed by lattice simulations, but currently the expansion coefficients are treated as universal parameters, which are adjusted to match the cross section measurements at the Tevatron [2, 3]. The calculation also applies to $c\bar{c}$ production in $ep$ collisions, but HERA measurements of $J/\psi$ polarizations tend to disagree with the NRQCD prediction [6]. These difficulties have led some authors to explore alternative power expansions of the long-distance interactions for the $c\bar{c}$ system [7]. There are also new QCD-inspired models, the gluon tower model [8] and the $k_T$-factorization model [9], that accommodate vector-meson cross sections at both HERA and the Tevatron and predict the vector-meson polarizations as functions of $p_T$. These authors emphasize that measuring the vector-meson polarizations as functions of $p_T$ is a crucial test of NRQCD.

The CDF II detector is described in detail elsewhere [3, 10]. In this analysis, the essential features are a muon system covering the central region of pseudorapidity, $|\eta| < 0.6$, and the tracking system, immersed in the 1.4 T solenoidal magnetic field and composed of a silicon microstrip detector and a cylindrical drift chamber called the central outer tracker (COT). The data used here correspond to an integrated luminosity of about 800 pb$^{-1}$ and were recorded between June 2004 and February 2006 by a dimuon trigger, which requires two opposite-charge muon candidates, each having $p_T > 1.5$ GeV/$c$.

Decays of vector mesons $V$ (either $J/\psi$ or $\psi(2S)$) → $\mu^+\mu^-$ are selected from dimuon events for which each track has segments reconstructed in both the COT and the silicon microstrip detector. The $p_T$ of each muon is required to exceed 1.75 GeV/$c$ in order to guarantee a well-measured trigger efficiency. The muon track pair is required to be consistent with originating from a common vertex and to have an invariant mass $M$ within the range 2.8 (3.4) < $M$ < 3.4 (3.9) GeV/$c^2$ to be considered as a $J/\psi$ ($\psi(2S)$) candidate. To have a reasonable polarization sensitivity, the vector-meson candidates are required to have $p_T \geq 5$ GeV/$c$ in the rapidity range $|y| = |\ln(E/p_T)| < 0.6$, where $E$ is the energy and $p_T$ is the momentum parallel to the beam direction of the dimuon system. Events are separated into a signal region and sideband regions, as indicated in Fig. 1. The fit to the data uses a double (single) Gaussian for the $J/\psi$ ($\psi(2S)$) signal and a linear background shape. The fits are used only to define signal and background regions. The signal regions are within 3$\sigma_V$ of the fitted mass peaks $M_V$, where $\sigma_V$ is the width obtained in the fit to the invariant mass distribution. Both the background distribution and the quantity of background events under the signal peak are estimated by events from the lower and upper mass sidebands. The sideband regions are $7\sigma_{J/\psi}$ ($4\sigma_{\psi(2S)}$) away from the signal region for $J/\psi$ ($\psi(2S)$).

For each candidate, we compute $ct = mL_{xy}/p_T$, where $t$ is the proper decay time and $L_{xy}$ is the transverse distance between the beam line and the decay vertex in the plane normal to the beam direction. The $ct$ distributions of the selected dimuon events are shown in Fig. 2. The $ct$ distribution of prompt events is a Gaussian distribution centered at zero due to finite tracking resolution. For $J/\psi$, the prompt events are due to direct production or the decays of heavier charmonium states such as $\chi_c$ and $\psi(2S)$; for $\psi(2S)$, the prompt events are almost entirely due to direct production since heavier charmonium states rarely decay to $\psi(2S)$ [11]. Both the $J/\psi$ and the $\psi(2S)$ samples contain significant numbers of events originating from long-lived $B$-hadron decays, as can be seen from the event excess at positive $ct$. We have measured the fraction of $B \rightarrow J/\psi + X$ events in the $J/\psi$ sample and found agreement with other results [2]. We select prompt events by requiring the sum of the squared impact parameter significances of the positively and negatively charged muon tracks $S = (\delta_u/\rho_u)^2 + (\delta_d/\rho_d)^2 \leq 8$. The impact parameter $\delta_0$ is the distance of closest approach of the track to the beam line in the transverse plane. Vector-meson candidates from $B$-hadron decays are selected by requiring $S > 16$ and $ct > 0.03$ cm. This requirement retains a negligible fraction of prompt events in the $B$ sample.

To measure the polarizations of prompt $J/\psi$ and $\psi(2S)$ mesons as functions of $p_T$, the $J/\psi$ events are analyzed in six $p_T$ bins and the $\psi(2S)$ events in three bins, shown in Table I. We determine the fraction of $B$-decay background remaining in prompt samples $f_{bkd}$ by subtracting the number of negative $ct$ events from the number of positive $ct$ events. Only a negligible fraction ($< 0.2\%$) of $B$ decays produce vector-meson events with negative $ct$. For both vector mesons, $f_{bkd}$ increases with $p_T$, as listed in Table I. The prompt polarization from the fitting algorithm is corrected for this contamination.
FIG. 1: Invariant mass distributions for (a) $J/\psi$ and (b) $\psi(2S)$ candidates. The curves are fits to the data. The solid (dashed) lines indicate the signal (sideband) regions.

FIG. 2: Sideband-subtracted $c t$ distributions for (a) $J/\psi$ and (b) $\psi(2S)$ events. The prompt Gaussian peak, positive excess from $B$-hadron decays, and negative tail from mismeasured events are shown. The dotted line is the reflection of the negative $c t$ histogram about zero.

The polarization information is contained in the distribution of the muon decay angle $\theta^*$, the angle of the $\mu^+$ in the rest frame of vector meson with respect to the vector-meson boost direction in the laboratory system. The decay angle distribution depends on the polarization parameter $\alpha$: 

$$ \frac{d N}{d \cos \theta^*} \propto 1 + \alpha \cos^2 \theta^* \quad (-1 \leq \alpha \leq 1). $$

For fully transverse (longitudinal) polarization, $\alpha = +1 (-1)$. Intermediate values of $\alpha$ indicate a mixture of transverse and longitudinal polarization.

A template method is used to account for acceptance and efficiency. Two sets of $\cos \theta^*$ distributions for fully polarized decays of $J/\psi$ and $\psi(2S)$ events, one longitudinal ($L$) and the other transverse ($T$), are produced with the CDF simulation program using the efficiency-corrected $p_T$ spectra measured from data \[3, 12\]. We use the muon trigger efficiency measured using data as a function of track parameters ($p_T$, $\eta$, $\phi$) to account for detector non-uniformities. The parametrized efficiency is used as a filter on all simulated muons. Events that pass reconstruction represent the behavior of fully polarized vector-meson decays in the detector.

The fitting algorithm \[5\] uses two binned $\cos \theta^*$ distributions for each $p_T$ bin, one made by $N_S$ events from the signal region (signal plus background) and the other made by $N_B$ events from the sideband regions (background).
The $\chi^2$ minimization is done simultaneously for both $\cos \theta^*$ distributions. The fitting algorithm includes an individual background term for each $\cos \theta^*$ bin, normalized to $N_{B}$. Simulation shows that the $\cos \theta^*$ resolution at all decay angles over the entire $p_T$ range is much smaller than the bin width of 0.05 (0.10 for $\psi(2S)$) used here. The data, fit, and template distributions for the worst fit (9% probability) in the $J/\psi$ data are shown in Fig. 3.

![Graph showing $\cos \theta^*$ distribution of data (points) and polarization fit for the worst $\chi^2$ probability bin in the $J/\psi$ data. The dotted (dashed) line is the template for fully L (T) polarization. The fit describes the overall trend of the data well.](image)

**FIG. 3:** $\cos \theta^*$ distribution of data (points) and polarization fit for the worst $\chi^2$ probability bin in the $J/\psi$ data. The dotted (dashed) line is the template for fully L (T) polarization. The fit describes the overall trend of the data well.

All systematic uncertainties are much smaller than the statistical uncertainties. Varying the $p_T$ spectrum in the simulation by 1σ changed the polarization parameter for $J/\psi$ at most by 0.002. A systematic uncertainty of 0.007 was estimated by the change in the polarization parameter when a modification was made on all trigger efficiencies by $\pm 1\sigma$. For $\psi(2S)$, the dominant systematic uncertainty came from the yield estimate because of the radiative tail and the large background. The total systematic uncertainties shown in Table 1 were taken to be the quadrature sum of these individual uncertainties. Other possible sources of systematic uncertainties - signal definition and $\cos \theta^*$ binning - were determined to be negligible. Corrections to prompt polarization from $B$-decay contamination were small, so that uncertainties on $B$-decay polarization measurements also had negligible effect. No $\phi$-dependence of the polarizations was observed.

The polarization of $J/\psi$ mesons from inclusive $B_u$ and $B_d$ decays was measured by the $BABAR$ collaboration [13]. In this analysis, the $B$-hadron direction is unknown, so we define $\theta^*$ with respect to the $J/\psi$ direction in the laboratory system. The resulting polarization is somewhat diluted. As discussed in Ref. 3, CDF uses a Monte Carlo procedure to adapt the $BABAR$ measurement to predict the effective $J/\psi$ polarization parameter. For the $J/\psi$ events with $5 \leq p_T < 30$ GeV/$c$, the CDF model for $B_u$ and $B_d$ decays gives $\alpha_{eff} = -0.145 \pm 0.009$, independent of $p_T$. We have measured the polarization of vector mesons from $B$-hadron decays. For $J/\psi$, we find $\alpha_{eff} = -0.106 \pm 0.033$ (stat) $\pm 0.007$ (syst). At this level of accuracy, a polarization contribution by $J/\psi$ mesons from $B_u$ and $b$-baryon decays cannot be separated from the effective polarization due to those from $B_u$ and $B_d$ decays. We also report the first measurement of the $\psi(2S)$ polarization from $B$-hadron decays: $\alpha_{eff} = 0.36 \pm 0.25$ (stat) $\pm 0.03$ (syst).

The polarization parameters for both prompt vector mesons corrected for $f_{bkd}$ using our experimental results on $\alpha_{eff}$ are listed as functions of $p_T$ in Table 1 and are plotted in Fig. 4. The polarization parameters for $J/\psi$ are negative over the entire $p_T$ range of measurement and become increasingly negative (favoring longitudinal polarization) as $p_T$ increases. For $\psi(2S)$, the central value of the polarization parameter is positive at small $p_T$, but, given the uncertainties, its behavior is consistent with the trend shown in the measurement of the $J/\psi$ polarization.

The polarization behavior measured previously with 110 pb$^{-1}$ [3] is not consistent with the results presented here. This is a differential measurement, and the muon efficiencies in this analysis are true dimuon efficiencies. In Ref. 3, they are the product of independent single muon efficiencies. The efficiency for muons with $p_T < 4$ GeV/$c$ is crucial for good polarization sensitivity. In this analysis, the muon efficiency varies smoothly from 99% to 97% over this range. In the analysis of Ref. [3], it varied from 93% to 40% with significant jumps between individual data points. Data from periods of drift chamber aging were omitted from this analysis because the polarization results were inconsistent with the remainder of the data. Studies such as this were not done in the analysis of Ref. 3. The systematics of the polarization measurement are much better understood in this analysis.

These polarization measurements for the charmed vector mesons extend to a $p_T$ regime where perturbative QCD should be applicable. The results are compared to the predictions of NRQCD and the $k_T$-factorization model in Fig. 4. The prediction of the $k_T$-factorization model is presented for $p_T < 20$ GeV/$c$ and does not include the contribution...
from the decays of heavier charmonium states for $J/\psi$ production. The polarizations for prompt production of both vector mesons become increasingly longitudinal as $p_T$ increases beyond 10 GeV/c. This behavior is in strong disagreement with the NRQCD prediction of large transverse polarization at high $p_T$. It is striking that the NRQCD calculation and the other models reproduce the measured $J/\psi$ and $\psi(2S)$ cross sections at the Tevatron, but fail to describe the polarization at high $p_T$. This indicates that there is some important aspect of the production mechanism that is not yet understood.
