ABSTRACT

The permeability test for permeable asphalt pavement cannot be applied to soil-based pavement in the field because this test erodes the ground surface due to the high positive applied pressure. Furthermore, the permeability test is based on the time required for a certain amount of water seepage to occur, which is not a hydraulic conductivity parameter that has a physical meaning. Therefore, in the present paper, we propose a measurement technique for water permeability and soil-water retentivity by field measurements using a suction infiltrometer. The results revealed that, even if the pavement layer is 10 cm in thickness, the proposed method can determine the field-saturated hydraulic conductivity. Furthermore, we determined the soil-water characteristic curve for soil-based pavement using the simultaneously measured water entry value.

Keywords: field saturated hydraulic conductivity, soil water characteristic curve, water entry value

1 INTRODUCTION

Recently, soil-based pavement has been used in Japan to mitigate the heat island effect and internal inundation. However, there is no in situ test method to evaluate the soil hydraulic soil properties before and after construction. Therefore, the present paper proposes a method for evaluating the field-saturated hydraulic conductivity and the soil-water characteristic curve for in situ soil-based pavement. Downward infiltration due to gravity and a suction gradient occur when water infiltrates the pavement surface [Wooding (1968) and Philip (1968)]. Reynolds and Elrick (1991) proposed that the hydraulic conductivity be determined when the water flow becomes steady. In the present study, we used the method of Reynolds and Elrick (1991) in order to determine the hydraulic conductivity of soil-based pavement.

2 DETERMINATION OF FIELD-SATURATED HYDRAULIC CONDUCTIVITY BY SUCTION INFILTRATION GENERAL SPECIFICATIONS

2.1 Field-saturated hydraulic conductivity of soil-based pavement

Soil-based pavement is formed by changing soil to an aggregated structure and improving its permeability. Micro pores in this type of pavement retain moisture and reduce the evaporation rate. Soil-based pavement has been used in several primary schools in Japan. Although there is a field permeability test for drainage in asphalt pavement, this test cannot determine the hydraulic conductivity. The field permeability test measures the time required for a certain amount of water to seep into the pavement. However, this method applies a high hydrostatic pressure (approximately 6 kPa) to the pavement surface, which will cause erosion of soil-based pavement. In contrast, the suction infiltration method applies negative pressure to the soil surface, so that erosion does not occur. Therefore, the suction infiltration method was used in the present study. The thickness of the soil-based pavement was approximately 10 cm. The applicability of this method was verified using numerical analysis.

2.2 Measurement principle

The rate of infiltration from a water supply disk is given as follows based on Wooding’s experimental results [Wooding (1968)]:

\[ Q = \pi R^2 k_{sw} (h) + 4R \phi(h) \]  (1)

where \( Q \) is the steady flow rate [cm³/s], \( R \) is the radius of the water supply disk [cm], \( \phi(h) \) is the matric flux potential [cm²/s], \( k_{sw}(h) \) is the unsaturated hydraulic conductivity [cm/s], \( k_f \) is the field-saturated hydraulic conductivity [cm/s], and \( h \) is the infiltration head [cm].

The first term in Eq. (1) indicates the downward infiltration due to gravity, and the second term indicates the matric suction. If the hydraulic conductivity of unsaturated soil is defined as follows:

\[ k_{sw}(h) = k_f \cdot \exp(ah) \]  (2)

then the matric potential can be written as:

\[ \phi(h) = \frac{2}{\rho g C_f} \int_0^h k_f \cdot \exp(ah) \, dh \]

https://doi.org/10.3208/jgssp.v07.012
\[ \phi(h) = \int k_{\psi}(h) \, dh = \int k_{q} \cdot \exp(ah) \, dh = \frac{k_{q} \cdot \exp(ah)}{a} \]  \hspace{1cm} (3)

By substituting Eq. (3) into Eq. (1), we obtain the following:

\[ \log_{e} \left( \frac{Q}{t} \right) = ah + \log_{e} \left( \frac{\pi R^2 + 4R}{a} \right) \cdot k_{q} \]  \hspace{1cm} (4)

where

\[ k_{q} = \frac{\exp \left[ \log_{e} \left( \frac{Q}{t} \right) \right]}{\pi R^2 + 4R/a} \]  \hspace{1cm} (5)

In order to determine the field-saturated hydraulic conductivity, the parameter \( a \) in Eq. (5) must be known. This can be experimentally determined from the intercept of a plot of \( \log_{e}(Q/t) \) against the negative pressure \( h \) [Nishimura (2017)], as shown in Fig. 1. The field-saturated hydraulic conductivity \( k_{fs} \) when \( h \) is zero can then be evaluated using Eq. (5).

2.4 Field-saturated hydraulic conductivity

(1) Experimental results

The amount of infiltration was measured under three different negative pressure heads (-4, -2, and -1 cm), and the amount of infiltration per unit time was calculated. Fig. 3 is plotted of \( Q \) against time. We judged an infiltration as saturated flow state when infiltration rate became constant. The field-saturated hydraulic conductivity \( k_{fs} \) is determined from the intercept and gradient in Eq. (4), and the results are shown in Fig. 4. It can be seen that \( k_{fs} \) of pavement (Point C) becomes higher than non-pavement (Point D).

(2) Relationship between pavement thickness and radius of water supply disk

The soil-based pavement was only about 10 cm thick, and in order to verify whether the measurements were finished before the infiltration depth (infiltration front) exceeds the thickness of the layer, we observed the infiltrating pressure head of the water supply, and the pressure can be controlled by vertically moving the control pipe.
the infiltration process using a half-section model with the same structure as the suction infiltrometer. Photograph 1 shows the infiltration process using the half-section model with the same structure as the suction infiltrometer. Figure 5 shows the time of arrival of the infiltration front at a depth of 10 cm for negative pressure heads of -3, -2, and -1 cm. The results show that the measurements were finished before the arrival of the infiltration front at a depth of 10 cm. To confirm this, the arrival time was numerically calculated using the software package Hydrus 2D. Figure 6 shows the dependence of the arrival time on the radius of the water supply disk for pressure heads of -0.5 and -2 cm. Based on the results, the greater the radius of the water supply disk, the shorter the arrival time of the infiltration.

3 PREDICTION OF SOIL-WATER CHARACTERISTIC CURVE FOR SUCTION INFILTRATION METHOD

3.1 Determination of water entry value

(1) Relationship between negative pressure supply and amount of infiltration

As previously noted, the amount of infiltration was measured for three negative pressure heads using the suction infiltration method. The relationship between the negative pressure supply and the amount of infiltration was analyzed after steady flow has occurred. Therefore, the negative pressure supply can be obtained when the velocity of the steady flow becomes zero, i.e., from the x-axis intercept of the graph in Fig. 7.
The negative pressure supply and the suction pressure on the pavement (soil) are assumed to be in balance, i.e., the pressure head when the saturated flux is zero, which corresponds to the water entry value (WEV) in Fig. 8. The WEV indicates the suction head for the soil-water characteristic curve (SWCC) in the wetting process, as shown in Fig. 9, and is equal to the reciprocal of the parameter $\alpha$ in the model of van Genuchten (1986). Therefore, the WEV for the soil-water characteristic curve is considered to be obtainable using the suction infiltration method.

**3.2 Determination of soil-water characteristic curve**

Although the WEV can be obtained using the suction infiltration method, it is necessary to determine the parameter $n$ in the van Genuchten model for assessment of the water retentivity. A method for determining $n$ is to use the van Genuchten model in conjunction with the suction infiltration method, as follows:

$$Se = \frac{1}{1 + (\alpha \cdot h_p)^{n-1/\theta}}$$  \hspace{1cm} (6)

Geometrically, parameters $\alpha$ and $n$ of van Genuchten model are independent of each other. However, from following reason, it seems that there is some relation to those affected by soil particle size and pore size. The smaller soil particle size is, the higher air entry value (AEV) with capillary height is. Therefore, parameter $\alpha_D$ of SWCC in drying process becomes smaller. On the other hands, as soil particle size decreases, pore size distribution becomes finer, so it can be easily inferred.

![Fig.9 Negative pressure supply and suction head.](image)

![Fig.10 Verification of WEV.](image)

![Fig.11.1 Relationship between parameter $\alpha_W$ and $n$ (Wetting process).](image)

![Fig.11.2 Relationship between parameter $\alpha_D$ and $n$ (Drying process).](image)
that \( n \) related to gradient (\( \Delta Se/\Delta h_p \)) of SWCC becomes smaller. Although this point is clear in some experimental examples, we investigated the relationship between the 12 kinds of soil property data using Hydrus-2D database.

Figure 11.1 shows relationship between \( \alpha_w \) and \( n \) of SWCC in wetting process. For reference, a relationship between \( \alpha_w \) and \( n \) of SWCC in drying process as shown in Fig.11.2. Regression equations are following:

- Wetting process
  \[
  n = 5.132 \cdot \alpha + 1.086 \quad (7)
  \]
- Drying process
  \[
  n = 10.264 \cdot \alpha + 1.086 \quad (8)
  \]

However, \( n \) in the wetting process and drying process is common, and \( \alpha_D = 0.5 \alpha_w \). In this present paper, we estimated \( n \) from Eq. (7) and \( \alpha \) obtained in the suction infiltration test, and it was possible to obtain the parameters as shown in Table 1. Where, \( \alpha_D \) is calculated as half of \( \alpha_w \). Figs. 12.1 and 12.2 show SWCC and the calculated unsaturated hydraulic conductivities using the van Genuchten model and Mualem and van Genuchten equation (Eq. (9)) using the parameters in Table 1.

\[
k_f = k_{f0} \cdot \left(1 - \left(1 - Se^{1/n}ight)^n\right)^m
\]

(9)

Where, \( m \) is 1-1/n.
From SWCC, it is judged that Point C (Soil-based pavement) is lower than Point D (Non-pavement) in water retentivity. Since Soil-based pavement is aggregated, the water retention of macro pores in soil-based pavement is evaluated as lower. In order to evaluate the agglomerated soil, it is considered that a multiple phase SWCC approach is required as in Durner's model (Duner (1994)).

A flow chart for obtaining the moisture characteristic curve from the suction infiltration test in situ is shown in Fig. 13.

4 CONCLUSION

The present study revealed the following:

(1) Even if soil-based pavement with a thickness of up to 10 cm, it can be used to evaluate the field-saturated hydraulic conductivity using the water supply disk with the 22.5 mm in radius.

(2) The WEV (or parameter $\alpha$ in the VG model) can be determined based on the negative pressure head in balance with the suction head for the pavement after reaching a steady flow.

(3) Geometrically, parameters $\alpha$ and $n$ of van Genuchten model are independent of each other, however, it seems that there is a relationship between $\alpha$ and $n$ due to relate pore structure of particle size.

(4) The hydraulic properties of soil-based pavement in the field can be determined using the suction infiltration method.
