ABSTRACT

We extend the abundance matching technique (AMT) to infer the satellite–subhalo and central–halo mass relations (MRs) of local galaxies as well as the corresponding satellite conditional mass functions (CSMFs). We use as inputs the observed galaxy stellar mass function (GSMF) decomposed into centrals and satellites and the ΛCDM distinct halo and subhalo mass functions. We explore the effects of defining the subhalo mass, $m_{\text{sub}}$, at the time of (sub)halo accretion ($m_{\text{acc,sub}}$) versus defining it at the time of observation ($m_{\text{obs,sub}}$); we also test the standard assumption that centrals and satellites follow the same MRs. We show that this assumption leads to predictions in disagreement with observations, especially when $m_{\text{obs,sub}}$ is used. We find that when the satellite–subhalo MRs are constrained by the satellite GSMF, they are always different from the central–halo MR: The smaller the stellar mass, the less massive the subhalo of satellites as compared to the halo of centrals of the same stellar mass. This difference is more dramatic when $m_{\text{obs,sub}}$ is used instead of $m_{\text{acc,sub}}$. On average, for stellar masses lower than $\sim 2 \times 10^{11} M_\odot$, the dark mass of satellites decreased by 60%–65% with respect to their masses at accretion time. We find that MRs for both definitions of subhalo mass yield CSMFs in agreement with observations. Also, when these MRs are used in a halo occupation model, the predicted two-point correlation functions at different stellar mass bins agree with observations. The average stellar–halo MR is close to the MR of central galaxies alone, and conceptually this average MR is equivalent to abundance matching the cumulative total GSMF to the halo + subhalo mass function (the standard AMT). We show that the use of $m_{\text{obs,sub}}$ leads to less uncertain MRs than $m_{\text{acc,sub}}$ and discuss some implications of the obtained satellite–subhalo MR. For example, we show that the tension between abundance and dynamics of Milky Way satellites in the ΛCDM cosmogony gives a value of $\sim 1.6$ in the faint-end slope of the GSMF upturns.

1. INTRODUCTION

In recent years, the abundance matching technique (AMT) has emerged as a simple yet powerful statistical approach to connect galaxies to halos without requiring knowledge of the underlying physics (e.g., Vale & Ostriker 2004; Kravtsov et al. 2004; Conroy et al. 2006; Shankar et al. 2006; Baldry et al. 2008; Conroy & Wechsler 2009; Drory et al. 2009; Behroozi et al. 2010, and references therein).

Briefly, the AMT assumes a one-to-one monotonic relationship between stellar and halo masses which can be constrained by matching the cumulative observed galaxy stellar mass function (GSMF) to the theoretical halo plus subhalo cumulative mass function. Interestingly enough, this simple approach successfully reproduces the observed spatial clustering of galaxies (e.g., Conroy et al. 2006; Moster et al. 2010). The AMT allows us to probe the average galaxy stellar–halo mass relation, $M_*(M_h)$ (hereafter SHMR), delivering very useful information for constraining models of galaxy evolution (e.g., Guo et al. 2010; Firman et al. 2010; Avila-Reese et al. 2011).

The above has motivated several authors to use the AMT extensively. For example, with the advent of large galaxy surveys at different redshifts, the AMT has been applied to constraining the evolution of the average SHMR (e.g., Conroy et al. 2006; Drory et al. 2009; Conroy & Wechsler 2009; Moster et al. 2010; Behroozi et al. 2010). As a natural extension, these studies have been combined with predicted average halo mass aggregation histories in order to infer average galaxy $M_*$ growth histories as a function of mass (Conroy & Wechsler 2009; Firmani 

Avila-Reese 2010; see Avila-Reese & Firmani 2011 for a review, and references therein). By including observational information about the gas content of galaxies, the AMT has also been used to constrain the baryon mass to $M_h$ relation of galaxies (Baldry et al. 2008; Rodríguez-Puebla et al. 2011). Finally, variants of the AMT, where instead of mass functions, circular velocity functions or functions of any other galaxy/halo global property are employed, have also been explored (e.g., Conroy et al. 2006; Blanton et al. 2008; Trujillo-Gomez et al. 2011).

The AMT has been commonly applied to the total (central plus satellite galaxies) GSMF matched against the total (distinct plus satellite) halo population. This approach has been criticized, because quite different average SHMRs are obtained for different proposed forms of the satellite–subhalo mass relation (SSMR, $M_*(m_{\text{sub}})$) and the central SHMR ($M_*(M_h)$; Neistein et al. 2011).

A common (questionable) assumption is that the SSMR is identical to the central SHMR. Under this assumption, it is also common to define subhalo mass at the time of accretion ($m_{\text{acc,sub}}$) rather than at the time of observation ($m_{\text{obs,sub}}$), when subhalos have lost a significant fraction of mass due to tidal stripping. The use of $m_{\text{acc,sub}}$ has been justified because this avoids the question of subhalo mass loss, and it is expected that the satellite $m_{\text{sub}}$ remains almost constant since its infall into the host halo. The projected two-point correlation function of galaxies is reproduced under

1 In order to make the distinction explicit, we shall use uppercase letters for the central galaxy and the distinct halo masses and lowercase letters for the satellite galaxy and subhalo masses.
these assumptions (Conroy et al. 2006; Moster et al. 2010). It should also be said that while the (local) SHMR for central galaxies has been determined (e.g., Mandelbaum et al. 2006; More et al. 2011), the SSMR for satellites/subhalos has not yet been discussed in detail in the literature.

In view of the above mentioned, some important questions arise: Why does using \( m_{\text{acc}}^{\text{sub}} \) instead of \( m_{\text{obs}}^{\text{sub}} \) lead to the correct clustering of galaxies? Does the \( m_{\text{acc}}^{\text{sub}} - M_* \) relation reproduce the observed satellite GSMF, the conditional stellar mass function, and spatial clustering of galaxies at the same time? Even more fundamentally, if it is not assumed that the SSMR is identical to the central SHMR, then what follows for the SSMR using either \( m_{\text{obs}}^{\text{sub}} \) or \( m_{\text{acc}}^{\text{sub}} \)? Does it deviate from the central SHMR?

In this paper we extend the common AMT to constrain both the central SHMR and the SSMR separately, as well as the average (total) SHMR. By construction, this formalism also allows us to predict the mean satellite conditional mass function (CSMF), i.e., the probability that satellites of a given stellar mass reside in distinct host halos of a given mass. We will (1) test whether the SSMR and the central SHMR follow the same shape, (2) discuss the consequences of defining the subhalo mass at accretion time versus at observed (present) time, and (3) check the self-consistency of our predicted present-day central SHMR and SSMR by comparison with the observed satellite CSMF and the spatial clustering of galaxies.

This paper is organized as follows: In Section 2, we present the AMT, focusing on the details of our extended abundance matching. In Section 3, we present the predicted SHMRs (Section 3.1) and satellite CSMFs (Section 3.2) for cases in which the SSMR is assumed equal to the central SHMR and those in which both mass relations are independently constrained. In Section 3.3, a halo occupation distribution (HOD) model is used to explore whether the predicted central SHMRs and SSMRs are consistent with the observed spatial clustering of galaxies. Section 4 is devoted to our conclusions and a discussion of the results and their implications.

All of our calculations are based on a flat \( \Lambda \)CDM cosmology with \( \Omega_\Lambda = 0.73, h = 0.7 \), and \( \sigma_8 = 0.84 \).

2. THE ABUNDANCE MATCHING TECHNIQUE

In this section, we describe the technique of matching abundances between central galaxies and halos and between satellite galaxies and subhalos, which we present here as an extension to the standard AMT.

2.1. Modeling the Central and Satellite GSMFs

To model the central GSMF, let \( P_{\text{cen}}(M_*|M_h) \) denote the probability distribution function that a distinct halo of mass \( M_h \) hosts a central galaxy of stellar mass \( M_* \). Then, the number density of central galaxies with stellar masses between \( M_* \) and \( M_* + dM_* \) is given by

\[
\phi_{\text{cen}}(M_*)dM_* = dM_* \int_0^\infty P_{\text{cen}}(M_*|M_h)\phi_h(M_h)dM_h. \tag{1}
\]

For the population of satellite galaxies in individual subhalos, let \( P_{\text{sat}}(m_*|m_{\text{sub}}) \) be the probability distribution function that a subhalo \( m_{\text{sub}} \) hosts a satellite galaxy of stellar mass \( m_* \). Thus, the average satellite CSMF (the number of satellite galaxies of stellar mass between \( m_* \) and \( m_* + dm_* \)) that reside in distinct host halos of mass \( M_h \), e.g., (Yang et al. 2009b) is

\[
\Phi_{\text{sat}}(m_*|M_h)dm_* = dm_* \int_0^\infty P_{\text{sat}}(m_*|m_{\text{sub}})\Phi_{\text{sub}}(m_{\text{sub}}|M_h)dM_h. \tag{2}
\]

where \( \Phi_{\text{sub}}(m_*|M_h) \) is the subhalo conditional mass function (subHMF, i.e., the number of subhalos of mass between \( m_{\text{sub}} \) and \( m_{\text{sub}} + dm_{\text{sub}} \) residing in host halos of mass \( M_h \); e.g., Boylan-Kolchin et al. 2010). A natural link between the satellite GSMF, \( \phi_{\text{sat}} \), and the distinct halo mass function (HMF, \( \phi_h \)) arises once the satellite CSMF is given:

\[
\phi_{\text{sat}}(m_*|M_h)dm_* = dm_* \int_0^\infty \Phi_{\text{sat}}(m_*|M_h)\phi_h(M_h)dM_h. \tag{3}
\]

Inserting Equation (2) into Equation (3) and rearranging terms, the satellite GSMF can be rewritten in terms of \( P_{\text{sat}}(m_*|m_{\text{sub}}) \):

\[
\phi_{\text{sat}}(m_*|m_{\text{sub}})dm_* = dm_* \int_0^\infty P_{\text{sat}}(m_*|m_{\text{sub}})\phi_h(M_h)dM_h. \tag{4}
\]

Equations (1) and (4) describe the abundance matching in its differential form for the central–halo and satellite–subhalo populations, respectively. The distribution probability \( P_{\text{cen}}(M_*|M_h) \) is defined by the mean \( M_*|M_h \) relation and a scatter of \( \sigma_c \) around it, while the distribution probability \( P_{\text{sat}}(m_*|m_{\text{sub}}) \), assumed to be independent of the host halo mass, is defined by the mean \( m_*|m_{\text{sub}} \) relation and a scatter of \( \sigma_s \) around it. Observe that once \( P_{\text{sat}}(m_*|m_{\text{sub}}) \) is given, the satellite CSMF is a prediction according to Equation (2).

Here, \( P_{\text{cen}}(M_*|M_h) \) and \( P_{\text{sat}}(m_*|m_{\text{sub}}) \) are modeled as lognormal distributions with a width (scatter around the stellar mass) assumed to be constant and the same for both centrals and satellites, \( \sigma_c = \sigma_s = 0.173 \) dex. Such a value was inferred for central galaxies from the analysis of general large group catalogs (Yang et al. 2009a, hereafter YMB09), and it is supported by recent studies of the kinematics of satellite galaxies (More et al. 2011). Regarding the intrinsic scatter of the satellite–subhalo relation, it has not been discussed in detail in the literature. While the exploration of this scatter is beyond the scope of the present paper, our conclusions will not depend critically on the assumed value for it, even if it is allowed to depend on host halo mass. We will further discuss this question in Section 4.2. Both \( m_*|m_{\text{sub}} \) and \( M_*|M_h \) are parameterized by the same modified two-power-law form proposed in Behroozi et al. (2010). This five-parameter function is quite general and, in the context of the AMT, has been shown to reproduce the main features of a Schechter-like GSMF.

2.2. The Relation to Standard Abundance Matching

In the standard AMT, the cumulative halo+subhalo mass function and the total observed cumulative GSMF are matched to determine the mass relation between halos and galaxies, which is assumed to be monotonic. In this context, no intrinsic scatter in the stellar mass at a given halo is assumed. In our approach, where the galaxy and halo populations are separated into centrals/satellites and distinct halo/subhalos, the latter

\footnote{Whenever we use \( m_{\text{sub}} \), we refer generically to subhalo mass. In practice, that can be either the mass at accretion time, \( m_{\text{acc}}^{\text{sub}} \), or that at observation (present-day) time, \( m_{\text{obs}}^{\text{sub}} \).}
entails that the probability distribution functions of centrals and satellites take the following particular forms: \( P_{\text{cen}}(M_i | M_h) = \delta(M - M_i(M_h)) \) and \( P_{\text{sat}}(M | m_{\text{sub}}) = \delta(M - m_s(m_{\text{sub}})) \), where \( M_i(M_h) \) and \( m_s(m_{\text{sub}}) \) are the mean central–halo and satellite–subhalo mass relations, and \( \delta \) is for the \( \delta \) Dirac function. The above “no scatter” probability distribution function for centrals applied in Equation (1) would lead us to conclude that the cumulative central GSMF, \( n_{\text{cen}}(>M_h) \), should match the cumulative distinct HMF, \( n_{\text{sub}}(>M_h) \). The same reasoning applies for satellites/subhalos. Therefore, we arrive at the standard AMT formulation:

\[
n_{s}(>M_h) = n_{s}(>M_h) + n_{\text{sub}}(>M_h),
\]

where \( n_{s}(>M_h) \equiv n_{\text{cen}}(>M_h) + n_{\text{sat}}(>M_h) \) is the total GSMF. The abundance matching can be applied to centrals/halos and satellites/subhalos separately, let us analyze now only the latter. Under the assumption that the \( m_s(m_{\text{sub}}) \) relation is independent of the host halo mass, it is clear that using either the abundance matching of all satellites and all subhalos, \( n_{\text{sat}}(>m_s) = n_{\text{sub}}(>m_{\text{sub}}) \), or the matching of their corresponding mean occupational numbers, one may find exactly the same \( m_s(m_{\text{sub}}) \) relation. In this sense, we state that matching abundances is equivalent to matching occupational numbers:

\[
\langle N_{s}(>m_{\text{sub}} | M_h) \rangle = \langle N_{\text{sub}}(>m_{\text{sub}} | M_h) \rangle \quad \iff \quad n_{\text{sat}}(>m_s) = n_{\text{sub}}(>m_{\text{sub}}).
\]

In the case where the probability distribution function \( P_{\text{sat}}(m_s|m_{\text{sub}}) \) includes scatter around the mean SSMR, as we consider here, the above conclusion remains the same, while \( P_{\text{sat}}(m_s|m_{\text{sub}}) \) is assumed to be independent of halo mass. In general, the inclusion of constant scatter in the galaxy–halo mass relations is not a conceptual problem for the AMT, but it slightly modifies the shape of the mass relations at the high-mass end (see Behroozi et al. 2010). Finally, note that if \( P_{\text{sat}}(m_s|m_{\text{sub}}) \) depends on \( M_h \), then \( \phi_{\text{sat}} \) may not be directly related to \( \phi_{\text{sub}} \) (see Equation (4)), and using either the matching of satellites and subhalo abundances or the matching of their corresponding occupational numbers would not lead to finding exactly the same \( m_s(m_{\text{sub}}) \).

**2.3. Inputs for Matching Abundances**

The inputs required for the procedure described above are the subhCMF, the distinct HMF, and the observed satellite and central GSMFs.

For the subhCMF, we use the results obtained in Boylan-Kolchin et al. (2010, hereafter BK10) based on the analysis of the Millennium-II Simulation. This is a re-simulation with the same resolution of a smaller volume of the Millennium Simulation. It consists of 2160³ particles, each of mass \( m = 6.885 \times 10^8 h^{-1} M_\odot \) in a periodic cube of length \( L = 100 h^{-1} \) Mpc. Observe that this mass particle resolution is around four orders of magnitude below the subhalo masses \( \mu \) and \( \mu_{\text{cat}}, a, b \) of the subhCMF. Therefore, we arrive at the standard AMT formulation:

\[
\langle N_{\text{sub}}(>m_{\text{sub}} | M_h) \rangle = \mu_0 \left( \frac{\mu}{\mu_1} \right)^a \exp \left( - \left( \frac{\mu}{\mu_{\text{cat}}} \right)^b \right),
\]

where \( \mu = m_{\text{sub}} / M_h \). For \( m_{\text{sub}} = m^{\text{acc}}_{\text{sub}}, \mu \) of the subhCMF, \( \mu_0, \mu_1, \mu_{\text{cat}}, a, b \) = (1.15 log \( M_h / 10^{12} M_\odot \), 0.01, 0.996, −0.935, 1.29).

Additionally, to be consistent with the same cosmology for which the subhalo subhCMF was inferred, we repeated all the analyses using the WMAP1 cosmology. We find that all our results are practically the same.

For the distinct HMF, we will use the formula given by Sheth & Tormen (1999). This formula provides a reasonable fit to the virial mass function at \( z = 0 \) measured in large cosmological N-body simulations (e.g., Klypin et al. 2011; Cuesta et al. 2008).

For our purpose, the decomposition of the GSMF and the CMFs into central and satellite galaxies is necessary. Using a large general group catalog (Yang et al. 2007) based on the data from the Sloan Digital Sky Survey (SDSS), YMB09 constructed and studied the decomposition of the GSMF and the CMFs into central and satellite galaxies. In that paper, a central galaxy was defined as the most massive galaxy in a group and the remaining galaxies were defined as satellites. For the mass completeness limit in the GSMF, they adopted the value as a function of redshift proposed in van den Bosch et al. (2008). They have also taken into account incompleteness in the group mass by considering an empirical halo-mass completeness limit (for details we refer the reader to YMB09).

Where necessary, halo masses are converted to match our definition of virial mass, and stellar masses are converted to the Chabrier (2003) initial mass function. In particular, YMB09 defined halo masses as being 180 times the background density; according to Giocoli et al. (2010, see their Appendix B), these halos are \( \sim 11\% \) larger than our definition of virial mass.

**2.4. Procedure and Uncertainties**

We constrain the parameters of the functions proposed to describe the central SHMR and SSMR by means of Equations (1) and (3) and by using the Powell’s direction set method in multidimensions for the minimization (Press et al. 1992). Note that in
our analysis the reported statistical errors in the GSMFs, as well as the intrinsic scatter in the mass relations, are taken into account. However, here we will not analyze rigorously the effects of uncertainties on the mass relations as well as their errors. Instead, we refer the reader to previous works (Moster et al. 2010; Behroozi et al. 2010; Rodríguez-Puebla et al. 2011).

Behroozi et al. (2010) studied in detail the uncertainties and effects on the average SHMR due to different sources of error like those in the observed GSMFs, including stellar mass estimates; those in the HMFs; those in the uncertainty of the cosmological parameters; and those in linking galaxies to halos, including the intrinsic scatter in this connection. These authors found that the largest uncertainty by far in the SHMR is due to systematic shifts in the stellar estimates. The second important source of uncertainty is the intrinsic scatter, which we take into account in our analysis. Other statistical and sample variance errors have negligible effects, at least for local galaxies. According to the Behroozi et al. (2010) study, the statistical and systematic uncertainties account for 1σ errors in the SHMR of approximately 0.25 dex at all masses, which is almost totally due to the uncertainty in stellar mass estimates. We also have explored here the effects of the subhalo CMF uncertainty on the SSMR. By using the 25% per dex in stellar mass variation reported by Giocoli et al. (2010) (instead of 15%), we find that the SSMR shifts in $m_*$ by only $\approx 0.04$ dex.

3. RESULTS

3.1. The Satellite GSMF and the SSMR

By means of the procedure described in Section 2, we calculate first the satellite GSMF (Figure 1) when the SSMR and the central SHMR are assumed to be the same, i.e., $m_*(m_{\text{sub}}) = M_*(M_h)$. This is equivalent to assuming that $P_{s|\text{sat}}(m_*,m_{\text{sub}}) = P_{\text{cen}}(M_*,M_h)$ if the intrinsic scatter of both relations is the same. We obtain the central SHMR by matching abundances of YMB09 central galaxies to distinct halos. This relation and the subHMF obtained from the theoretical subCFMF (Equation (8)) are used to infer the satellite GSMF (Equation (4)). The satellite GSMF is presented for the two cases of subhalo mass definition: $\phi_{\text{sat},\text{acc}}$ when $m_{\text{acc}}$ is used (long-dashed line) and $\phi_{\text{sat},\text{obs}}$ when $m_{\text{obs}}$ is used (short-dashed line). The observational results of YMB09 are plotted as well.

Under the assumption that $m_*(m_{\text{sub}}) = M_*(M_h)$, the predicted number density of satellites at masses below the knee is underestimated on average by a factor of $\sim 2$ when using $m_{\text{acc}}$ and $\sim 5$ when using $m_{\text{obs}}$. Note that the former is closer to the YMB09 data. The reason is simply because the normalization of the $m_{\text{sub}}$ subHMF is higher and closer to the distinct HMF than the normalization of the $m_{\text{sub}}$ subHMF. Therefore, satellites of equal $m_*$ are expected to have a higher number density when using the accreted-time ($m_{\text{acc}}$) subHMF compared to using the observed-time ($m_{\text{obs}}$ present-day) subHMF.

However, neither $m_{\text{acc}}$ nor $m_{\text{obs}}$ are able to reproduce the observed satellite GSMF, and the discrepancy is due to the basic assumption of a common stellar mass–(sub)halo mass relation for centrals and satellites. In the case where $m_{\text{sub}} = m_{\text{acc}}$, this is equivalent to assuming that the SSMR is independent of redshift. In fact, this cannot be the case since the satellite mass $m_*$ hardly will remain the same since it was accreted to the present epoch. On the other hand, when using $m_{\text{sub}} = m_{\text{obs}}$, that the SSMR is equal to the central SHMR implies that both have evolved, on average, identically. This cannot be the case because it is evident that the population of subhalos evolved differently from distinct halos, mainly by losing mass due to tidal stripping (e.g., Kravtsov et al. 2004; van den Bosch et al. 2005).

The next step in our analysis is to allow the SSMR and central SHMR to be different, i.e., $m_*(m_{\text{sub}}) \neq M_*(M_h)$. In this case, $P_{s|\text{sat}}(m_*,m_{\text{sub}})$ is determined by means of Equation (4) using the YMB09 satellite GSMF as a constraint. For the subCFMF, we again use both definitions of subhalo mass, $m_{\text{acc}}$ and $m_{\text{obs}}$. For illustrative purposes, we present the resulting satellite GSMF for the case in which $m_{\text{obs}}$ was used (solid line in Figure 1; an almost identical GSMF is obtained when $m_{\text{acc}}$ is used).

As shown in Figure 2, the SSMRs obtained by using $m_{\text{acc}}$ (long-dashed line) and $m_{\text{sub}}$ (solid line) are quite different. The central SHMR (dot-dashed line) is the same for both cases. The error bar in the left panel shows a 1σ uncertainty of 0.25 dex in the normalization of the mass relations. This is roughly the uncertainty estimated by Behroozi et al. (2010) taking into account all the systematical and statistical sources of errors (see Section 2.4).

When using the accretion-time subhalo mass, $m_{\text{acc}}$, we note that the resulting SSMR at log($m_*/M_\odot$) $< 11$ systematically lies above the central SHMR, with differences in the stellar-mass axis (halo-mass axis) of $\sim 0.5$ dex at the smallest masses. For log($M_*/M_\odot$) $> 11$ this trend is inverted, but the differences between central and satellites are very small. However, the relation obtained this way should be taken with caution. By construction, each $m_{\text{acc}}$ is itself a cumulative distribution of all the objects accreted in a time interval $\Delta t$. Therefore, such an SSMR entails that all accreted objects of mass $m_{\text{acc}}$ would evolve, on average, to host the same $m_*$ despite having been accreted at different times. We discuss this in Section 4.1.

When using the observation-time (present-day) subhalo mass, $m_{\text{obs}}$, we have log($m_*/M_\odot$) $> 11$ the discrepancy is due to the basic assumption of a common stellar mass–halo mass relation for centrals and satellites. In the case where $m_{\text{sub}} = m_{\text{acc}}$, this is equivalent to assuming that the SSMR is independent of redshift. In fact, this cannot be the case since the satellite mass $m_*$ hardly will remain the same since it was accreted to the present epoch. On the other hand, when using $m_{\text{sub}} = m_{\text{obs}}$, that the SSMR is equal to the central SHMR implies that both have evolved, on average, identically. This cannot be the case because it is evident that the population of subhalos evolved differently from distinct halos, mainly by losing mass due to tidal stripping (e.g., Kravtsov et al. 2004; van den Bosch et al. 2005).

The next step in our analysis is to allow the SSMR and central SHMR to be different, i.e., $m_*(m_{\text{sub}}) \neq M_*(M_h)$. In this case, $P_{s|\text{sat}}(m_*,m_{\text{sub}})$ is determined by means of Equation (4) using the YMB09 satellite GSMF as a constraint. For the subCFMF, we again use both definitions of subhalo mass, $m_{\text{acc}}$ and $m_{\text{obs}}$. For illustrative purposes, we present the resulting satellite GSMF for the case in which $m_{\text{obs}}$ was used (solid line in Figure 1; an almost identical GSMF is obtained when $m_{\text{acc}}$ is used).

As shown in Figure 2, the SSMRs obtained by using $m_{\text{acc}}$ (long-dashed line) and $m_{\text{sub}}$ (solid line) are quite different. The central SHMR (dot-dashed line) is the same for both cases. The error bar in the left panel shows a 1σ uncertainty of 0.25 dex in the normalization of the mass relations. This is roughly the uncertainty estimated by Behroozi et al. (2010) taking into account all the systematical and statistical sources of errors (see Section 2.4).

When using the accretion-time subhalo mass, $m_{\text{acc}}$, we note that the resulting SSMR at log($m_*/M_\odot$) $< 11$ systematically lies above the central SHMR, with differences in the stellar-mass axis (halo-mass axis) of $\sim 0.5$ dex (0.2 dex) at the smallest masses. For log($M_*/M_\odot$) $> 11$ this trend is inverted, but the differences between central and satellites are very small. However, the relation obtained this way should be taken with caution. By construction, each $m_{\text{acc}}$ is itself a cumulative distribution of all the objects accreted in a time interval $\Delta t$. Therefore, such an SSMR entails that all accreted objects of mass $m_{\text{acc}}$ would evolve, on average, to host the same $m_*$ despite having been accreted at different times. We discuss this in Section 4.1.

When using the observation-time (present-day) subhalo mass, $m_{\text{obs}}$, we have log($m_*/M_\odot$) $> 11$ the discrepancy is due to the basic assumption of a common stellar mass–halo mass relation for centrals and satellites. In the case where $m_{\text{sub}} = m_{\text{acc}}$, this is equivalent to assuming that the SSMR is independent of redshift. In fact, this cannot be the case since the satellite mass $m_*$ hardly will remain the same since it was accreted to the present epoch. On the other hand, when using $m_{\text{sub}} = m_{\text{obs}}$, that the SSMR is equal to the central SHMR implies that both have evolved, on average, identically. This cannot be the case because it is evident that the population of subhalos evolved differently from distinct halos, mainly by losing mass due to tidal stripping (e.g., Kravtsov et al. 2004; van den Bosch et al. 2005).
The lower the mass is. This is consistent with the picture that most massive subhalos, on average, fell into larger halos very recently and have not had time to lose significant amounts of mass due to tidal stripping, in contrast to the lowest mass subhalos.

This also suggests that the SSFR for both definitions of subhalo mass should tend to the central SSFR at the high-mass end, but this is not the case as seen in Figure 2, where small differences remain. The possible reasons are that, first, the intrinsic scatter around the stellar–(sub)halo mass relations is actually lower for the former than for the latter (here we assume it to be the same for satellites and centrals, see Section 4.2). Second, the YMB09 satellite SSFM may underestimate the true satellite mass function at large masses (see also Skibba et al. 2011).

Fiber collisions could introduce some systematic errors that may affect the YMB09 group catalog. To study the impact of this possible systematic error, YMB09 divided their group catalog into two samples: one that uses galaxies with known redshifts, and another that includes galaxies that lack redshifts due to fiber collisions. When they compared the corresponding satellite-SSFM from both samples (see their Figure 6), they found that the sample for which the correction for fiber collisions has been taken into account has a higher amplitude of the SSFM than when this correction was not applied, especially in low-mass halos. However, the difference is very marginal and well within the error bars. We conclude that fiber collisions in the YMB09 group catalog are not a serious source of systematics that are able to affect our conclusions. Regarding completeness and contamination of their group catalog (for details see Yang et al. 2007), 80% have a completeness greater than 0.6, while 85% have a contamination lower than 0.5. In terms of purity, their halo-based group finder is consistent with the ideal situation.

Finally, we note that the mass relation usually obtained by matching abundances between the total SSFM and the halo plus subHMF, in light of the decomposition into centrals and satellites, could be interpreted as a density-weighted average SSFR:

\[
\langle M_*(\phi) \rangle = \frac{\phi_{\text{sub}}(M) M_*(M)}{\int \phi_{\text{sub}}(M) \delta(M) dM} + \frac{\phi_{\text{DM}}(M) M_*(M)}{\int \phi_{\text{DM}}(M) \delta(M) dM},
\]

where \(\phi_{\text{DM}}(M) = \phi_{\text{sub}}(M) + \phi_b(M), \) \(M_*(M)\) is the mean SSFR, and \(M_*(M)\) is the mean central SSFR. This relation is plotted in Figure 2 with short-dash-dotted and short-dashed lines when using \(m_{\text{sub}}\) and \(m_{\text{obs}}\) respectively. Since most galaxies in the YMB09 catalog are centrals, the central SSFR is very close to the density-weighted average SSFR. For comparison, we plotted the Behroozi et al. (2010) average mass relation (filled circles), which is in excellent agreement with our density-weighted average SSFR when using the accreted-time subhalo mass, \(m_{\text{acc}}\).

Observe that differences between the satellite and the average (total) mass relations are small when \(m_{\text{acc}}\) is used, while differences become dramatic when \(m_{\text{obs}}\) is used. The above explains why, under the assumption that \(m_*(m_{\text{obs}}) = M_*(M)\), the resulting satellite SSFM are closer to observations. On the other hand, since the \(m_{\text{sub}}\) subHMF has a higher normalization than the \(m_{\text{obs}}\) subHMF, the above shows that when assuming \(m_*(m_{\text{obs}}) = M_*(M)\), we should expect the resulting satellite SSFM to be significantly below the observed satellite SSFM.

### 3.1.1. Comparison with Other Observational Inferences

In the right panel of Figure 2, we plot some observational inferences of halo and subhalo masses as a function of stellar mass. The inferred \(M_*(M)\) of central galaxies from staked weak-lensing studies using the SDSS (Mandelbaum et al. 2006) are shown as filled circles with error bars. Mandelbaum et al. (2006) reported the data for blue and red galaxies separately. We estimated the average mass relation for central galaxies as \(M_*(M) = f_b(M_*) \langle M_b \rangle_b + f_r(M_*) \langle M_r \rangle_r\), where \(f_b(M_*)\) and \(f_r(M_*)\) are the blue and red galaxy fractions in the sample, and \(\langle M_b \rangle_b\) and \(\langle M_r \rangle_r\) are the corresponding blue and red mass relations. The inferred \(\langle \log(M_*) \rangle (M_b)\) for
central galaxies from staked kinematics of satellites (More et al. 2011) are plotted as the dashed area indicating 68% confidence. Our inferred central SHMR (dot-dashed curve) is consistent with the weak-lensing inferences at all masses and with the satellite kinematics inferences at masses $M_\text{s} \gtrsim 10^{11} M_\odot$; for smaller masses, our halo masses are a factor up to $\sim 2$ smaller than the satellite kinematics inferences. In fact, it was already noted that using the kinematics of satellite galaxies yields halo masses around low-mass galaxies that are systematically larger than most other methods, especially for red central galaxies (More et al. 2011; Skibba et al. 2011; Rodríguez-Puebla et al. 2011).

Regarding satellites, unfortunately, there are no direct inferences of their subhalo masses. Some model-dependent estimates based on dynamical observations of Milky Way (MW) satellites were presented in the literature. For example, using the line-of-sight velocity dispersions measured for the brightest spheroidal dwarf galaxies, Strigari et al. (2007, 2010) determined their masses within their tidal radii. These dynamical masses, plotted in Figure 2 (filled squares and triangles, respectively), are expected to be of the order of $m_{\text{sub}}^{\text{obs}}$. We also plot an estimate of the mass at the tidal radius for the Large Magellanic Cloud (filled pentagon; Weinberg 1999). The SSMRs constrained here do not extend to the small masses of MW satellites, but we plot their extrapolations to these masses (dashed curves). The gray dot-dashed curve will be discussed in Section 4.3.

3.2. The Satellite CSMF

From the approach described in Section 2, another statistical quantity that deserves study is the satellite CSMF (Equation (2)). We calculate the mean halo-density-weighted CSMF at the $[M_{h1}, M_{h2}]$ bin as

$$\langle \Phi_s \rangle = \frac{\int_{M_{h1}}^{M_{h2}} \Phi_s(M_s | M_h) \phi_h(M_h) dM_h}{\int_{M_{h1}}^{M_{h2}} \phi_h(M_h) dM_h}. \quad (10)$$

This quantity has been inferred from observations by YMB09, again using their SDSS galaxy catalog (filled circles with error bars in Figure 3).

First, we consider again the case assuming $m_{s}(m_{\text{sub}}) = M_h(M_h)$. When $m_{\text{sub}}$ is defined at the observation time, the resulting CSMFs are lower than the YMB09 CSMFs by a factor of $\sim 5$ in the power-law regime (roughly the same factor by which $\phi_{\text{sat,obs}}$ is lower than the YMB09 observed satellite GSMF). Similarly, when $m_{\text{sub}}$ is defined at the accretion time, the predicted CSMFs in the power-law regime are below the YMB09 CSMFs by nearly the same factor, $\sim 2$, that $\phi_{\text{sat,acc}}$ lies below the satellite GSMF. The normalization of the CSMF increases faster with $M_h$ when $m_{\text{sub}}^{\text{obs}}$ is used instead of $m_{\text{sub}}^{\text{acc}}$. This is because we allow the $m_{\text{sub}}^{\text{acc}}$ subhCMF normalization to vary with host halo mass, while the $m_{\text{sub}}^{\text{obs}}$ subhCMF normalization is independent of host halo mass. The black continuous ($m_{\text{sub}}^{\text{obs}}$) and blue long-dashed ($m_{\text{sub}}^{\text{acc}}$) lines in Figure 3 (almost indistinguishable from one another) are the predictions when $P_{\text{sat}}(m_s | m_{\text{sub}})$ has been constrained by means of the observed satellite GSMF. The agreement of the predicted satellite CSMFs for both $m_{\text{sub}}^{\text{obs}}$ and $m_{\text{sub}}^{\text{acc}}$ with the YMB09 CSMFs is now remarkable at all halo mass bins for low/intermediate stellar masses. However, as above, the normalization of the CSMFs increases faster when $m_{\text{sub}} = m_{\text{sub}}^{\text{obs}}$ than when $m_{\text{sub}} = m_{\text{sub}}^{\text{acc}}$; the differences between both cases at any mass are less than 0.05 dex, within the error bars of the observational data.

Despite the overall agreement, for halo mass bins lower than $\sim 10^{13} M_\odot$, the number of massive satellite galaxies is...
overestimated, especially at the lowest $M_h$ bins. A possible reason for this is the assumption that the scatter in $P_{\text{sub}}(m_s|m_{\text{sub}})$ is constant, while in reality it could depend on $M_h$ as well as on $m_{\text{sub}}$. However, the probability of finding massive satellite galaxies in halos less massive than $\sim 10^{13} M_\odot$ is low, and they do not contribute significantly to the mean total density of satellite galaxies. Therefore, this assumption does not change our conclusions; see also Section 4.

Our analysis shows that, assuming $P_{\text{sub}}(m_s|m_{\text{sub}}) = P_{\text{cen}}(M_s|M_h)$, the resulting satellite CSMFs are not consistent with observations. Instead, when $P_{\text{sub}}(m_s|m_{\text{sub}})$ is independently constrained using the observed satellite GSMF, there is clear agreement, no matter what definition of $m_{\text{sub}}$ was employed for the subhCMF.

### 3.3. Abundance Matching and Clustering

It has been noted in the literature that the average (total) SHMR obtained with the standard AMT is consistent with the observed spatial clustering of galaxies (Conroy et al. 2006; Moster et al. 2010). We will now test whether this is the case for the mass relations of central and satellite galaxies obtained here with our extended AMT. We will compute the galaxy projected correlation function by means of an HOD model for each of the mass relation obtained in Section 3.1.

An HOD model is a statistical tool mainly used to describe the clustering of galaxies (e.g., Berlind & Weinberg 2002; Cooray & Sheth 2002; Yang et al. 2003, 2012; Zehavi et al. 2005, 2011; Leauthaud et al. 2011, 2012 and references therein). In contrast to the AMT, which is a quasi-empirical tool, an HOD employs modeling motivated by results of cosmological $N$-body (e.g., Kravtsov et al. 2004) and hydrodynamical (e.g., Zheng et al. 2005) simulations.

In short, an HOD model describes the probability that a halo of mass $M_h$ hosts a number of galaxies $N$ with stellar masses greater than $M_*$. Once the occupational numbers are defined, the two-point correlation function can be computed assuming that the total mean number of galaxy pairs is the contribution of all pairs coming from galaxies in this same halo (one-halo term) and pairs from different halos (two-halo term). For a detailed description of the HOD model we employ here, see the Appendix.

First, consider the case when $P_{\text{sub}}(m_s|m_{\text{sub}}) = P_{\text{cen}}(M_s|M_h)$. The short-dashed curves in Figure 4 show the projected correlation functions in five stellar mass bins for the case in which the $m_{\text{sub}}$ subhCMF was used. The Yang et al. (2012) galaxy projected correlation functions from the DR7 SDSS are plotted as filled circles with error bars. The resulting correlation functions are clearly below observations, mainly in the one-halo term. This is because using $m_{\text{sub}}$ underestimates the satellite GSMF and CSMF, resulting in a strong deficit of satellite galaxies. Observe that if $N_s \sim 0$, then $N \sim N_c$ and therefore, $b_s(M_s) \sim (b(M_h))$ where $b(M_h)$ is the mean weighted halo bias function, see Equation (A5).

When using the subhCMF for $m_{\text{sub}}$ instead of $m_{\text{obs}}$ (dot-short-dashed curves), the agreement with the observed correlation functions is better, though at scales where the one-halo term dominates, the predictions are still below observations. This is, again, because the satellite GSMF and CSMF are underestimated in this case. We remark that using the (average or total) SHMR obtained with the standard AMT in the HOD model by matching the total GSMF to the total halo+subhalo mass function (in the case of $m_{\text{obs}}$) leads to excellent agreement with the observed correlation functions, a result that is well known. However, in this case the SSMR is not constrained; it is instead implicitly assumed to be equal to the central SHMR (for
m_{\text{sub}}^{\text{acc}}). With our extended AMT, we can explicitly separate both mass relations. When they are assumed to be equal and the central SHMR is constrained with the central GSMF, then we obtain the predictions already shown, in particular the correlation functions. The fact that the predicted correlation functions, when \( m_{\text{sub}}^{\text{acc}} \) is used, are close to those predicted in the standard AMT (and to the observed ones) is because the central and average SHMR are indeed close, as discussed in Section 3.1, see Figure 2.

Thus, under the assumption that \( P_{\text{sat}}(m_s|m_{\text{sub}}) = P_{\text{cen}}(M_s|\theta) \), the observed clustering of galaxies is better reproduced when the subhalo mass in abundance matching is defined as \( m_{\text{sub}}^{\text{acc}} \) rather than \( m_{\text{sub}}^{\text{obs}} \). Nevertheless, even in the former case, the agreement with observations is only marginal.

We now turn the analysis to the cases in which the SSMR is not assumed to be equal to the central SHMR. The black solid and blue long-dashed lines in Figure 4 show the predicted correlation functions in the cases in which either \( m_{\text{sub}}^{\text{obs}} \) or \( m_{\text{sub}}^{\text{acc}} \) were used. Both cases lead to very similar results and agree very well with observations.

Therefore, the HOD model combined with the central and satellite mass relations independently constrained with the extended AMT is able to reproduce the observed correlation functions, no matter if \( m_{\text{sub}}^{\text{obs}} \) or \( m_{\text{sub}}^{\text{acc}} \) are used. This successful prediction is a consequence of the good agreement obtained between our predicted satellite CSMFs and those inferred from observations (Section 3.2 and Figure 3).

### 4. SUMMARY AND DISCUSSION

In this paper, we extend the AMT in order to constrain both the central stellar–halo and the satellite–subhalo mass relations separately, using as an input (1) the distinct HMF and subHMF and (2) the observed central and satellite GSMFs. Our formalism, by construction, also predicts the satellite CSMFs as a function of host halo mass; when applied to an HOD model, it allows us to predict the spatial correlation functions. We present results for the cases in which the SSMR is assumed to be equal to the central SHMR, \( P_{\text{sat}}(m_s|m_{\text{sub}}) = P_{\text{cen}}(M_s|\theta) \), and when both mass relations are constrained independently (i.e., it is not assumed that \( P_{\text{sat}}(m_s|m_{\text{sub}}) = P_{\text{cen}}(M_s|\theta) \)). Our analysis is carried out for subhalo masses defined at accretion time, \( m_{\text{sub}}^{\text{acc}} \), and at the observed time (present day), \( m_{\text{sub}}^{\text{obs}} \). The main results and conclusions are as follows:

1. Assuming that the mass relation between satellites and subhalos is identical to the mass relation between central and distinct halos (including their intrinsic scatter), \( P_{\text{sat}}(m_{\text{sub}}|m_s) = P_{\text{cen}}(M_{\text{sub}}|M_s) \), the predicted satellite GSMF, CSMFs, and projected two-point correlation functions lie below those obtained from observations for both definitions of \( m_{\text{sub}} \), though the disagreements are small when \( m_{\text{sub}} = m_{\text{sub}}^{\text{acc}} \) (Figures 1, 3, and 4). We conclude that assuming \( P_{\text{sat}}(m_{\text{sub}}|m_s) = P_{\text{cen}}(M_{\text{sub}}|M_s) \) leads to predictions in disagreement with observations, especially when \( m_{\text{sub}}^{\text{acc}} \) is used.

2. When the SSMR is no longer assumed to be equal to the central SHMR and instead is constrained by means of the observed satellite GSMF, the predicted satellite CSMFs and projected correlation functions agree in general with observations, both for \( m_{\text{sub}}^{\text{obs}} \) and \( m_{\text{sub}}^{\text{acc}} \). However, for halo masses lower than \( \sim 10^{13} M_{\odot} \), the number of very massive (rare) satellites is overpredicted.

3. The resulting \( m_{\text{sub}} - m_s \) relations when using either \( m_{\text{sub}}^{\text{obs}} \) or \( m_{\text{sub}}^{\text{acc}} \) are quite different from each other, and in each case are different from the central SHMR (Figure 2). For a given stellar mass, the satellite–subhalo mass is smaller than the central–halo mass, and the mass difference increases the lower the mass is. These differences are dramatic when \( m_{\text{sub}}^{\text{obs}} \) is used.

4. Our density-weighted average (centrals + satellites) SHMRs are close to the central SHMR when either \( m_{\text{sub}}^{\text{obs}} \) or \( m_{\text{sub}}^{\text{acc}} \) is used (central galaxies dominate in the YMB09 catalog). Such an average SHMR coincides conceptually with the one inferred from matching the total (centrals + satellites) cumulative GSMF and the halo + subhalo cumulative mass function (standard AMT).

### 4.1. On the Inference of the SSMR and Its Implications for the Average Mass Relation

The conclusions listed above can be well understood by examining the basic ideas behind the extended AMT, as we show in Section 2.2. Essentially, matching abundances of satellite galaxies to subhalos is equivalent to matching their corresponding occupational numbers, that is

\[
\langle N_s(>m_s|M_h) \rangle = \langle N_{\text{sub}}(>m_{\text{sub}}|M_h) \rangle.
\]  

The opposite is also true: Matching their corresponding occupational numbers is equivalent to matching their abundances. This is an important result because it shows that once \( P_{\text{sat}}(m_s|m_{\text{sub}}) \) (and \( P_{\text{cen}}(M_s|\theta) \)) is properly constrained, we will obtain the correct conditional mass functions and, consequently, the correct spatial clustering for galaxies.

The above means that there is a unique \( m_{\text{sub}}(m_s) \) relationship for each definition of \( m_{\text{sub}} \), which depends solely on \( \langle N_{\text{sat}}(>m_{\text{sub}}|M_h) \rangle \). Because of this uniqueness, it follows that the \( m_{\text{sub}}^{\text{obs}}(m_s) \) and \( m_{\text{sub}}^{\text{acc}}(m_s) \) relations should be different, and any incorrect assumption on each one of these relations will lead to inconsistencies in the conditional mass functions and spatial clustering of galaxies, for example, those that we have found here when \( P_{\text{sat}}(m_s|m_{\text{sub}}) \) was assumed to be equal to \( P_{\text{cen}}(M_s|\theta) \). Under this assumption, when \( m_{\text{sub}}^{\text{acc}} \) was used, the inconsistencies were actually small. This is because in this case the “incorrect” assumption for the SSMR is actually not too far from the “correct” result obtained when \( P_{\text{sat}}(m_s|m_{\text{sub}}^{\text{acc}}) \) is independently constrained (compare the dot-dashed and solid green curves in Figure 2), contrary to what happens when \( m_{\text{sub}}^{\text{obs}} \) is used.

It is important to note that in the standard AMT, only the average SHMR is constrained (using the total GSMF), leaving the SSMR unconstrained, something that on its own introduces a large uncertainty in the average SHMR (see Neistein et al. 2011). We have shown that such an average SHMR is conceptually equal to the density-weighted average mass relation obtained here from the observationally constrained central SHMR and SSMR. Therefore, our resulting average mass relation is expected to be less uncertain than previous determinations. On the other hand, this average mass relation is expected to be close to the central SHMR because most of the galaxies in the observational catalog used are centrals.

We conclude that in order to properly infer the SSMR and the central SHMR at the same time, and in this way reduce the uncertainty in the average SHMR, more observational constraints than the total GSMF are necessary. The most obvious and direct way is the GSMF decomposed into central and satellite galaxies, something that was provided by YMB09. However, observe that, according to Equation (11), the satellite CSMFs or the clustering of galaxies, modulo the observational...
errors, provide observational constraints that lead to similar inferences of the SSMR, because of the uniqueness of this relation for a given well defined \( (N_{\text{sub}} > m_{\text{sub}} | M_h) \) (see above).

Finally, we note that obtaining the SSMR for the subhalo mass defined at the accretion time introduces uncertainties due to our ignorance about evolutionary processes of the stellar mass since accretion. This does not happen when the SSMR is obtained for both the satellite and subhalo masses defined at the same epoch, for instance the present time. When matching abundances for the \( m_{\text{acc}} \) case, the fact that (1) \( m_{\text{acc}} \) is itself a cumulative distribution of all objects accreted over a period of time and that (2) \( m_s \) may have changed between accretion and observation are not taken into account. In other words, it is implicitly assumed that the satellite stellar mass stops evolving soon after accretion. In reality, the situation is actually quite complex in the sense that, depending on the accretion time and the orbit of the satellites, the evolution of their stellar masses is diverse, with some of them quenched early and others actively evolving, perhaps in some cases as the central ones of the same mass (see, e.g., Wetzel et al. 2012 for semi-empirical inferences on such a complexity of galaxy evolution in groups). This diversity introduces an intrinsic uncertainty in the results. Such an uncertainty might be accounted for in the probability distribution functions: \( P(m_s | m_{\text{acc}}, z) \), which gives the probability that a satellite accreted at epoch \( z \) evolves, on average, to the observed satellite \( m_s \), and \( P(m_{\text{acc}} | m_{\text{sub}} | z) \), which gives the probability that a subhalo \( m_{\text{acc}} \) hosts a galaxy of mass \( m_{\text{acc}} \) at the time of accretion. Now, the satellite CSMF (Equation (2)) can be written as (Mo et al. 2010)

\[
\Phi_s(m_s|M_h) = \int \int P(m_s|m_{\text{acc}}, z) P(m_{\text{acc}} | m_{\text{sub}} | z) \times \Phi(m_{\text{sub}} | M_h, z) dm_{\text{sub}} dm_{\text{acc}} dz.
\]  

Note that in our analysis in Section 3.1, we implicitly assume that the stellar mass of satellite galaxies does not change once they become satellites, i.e., \( P(m_s | m_{\text{acc}}, z) = \delta(m_s - m_{\text{acc}}, z) \), and that \( P(m_{\text{acc}} | m_{\text{sub}} | z) \) is independent of redshift. Thus, the application of the AMT to infer the satellite CSMF and the \( m_s - m_{\text{sub}} \) relation for subhalo mass defined at its accretion time formally requires more observational constraints at higher redshifts. This is a problem already faced by previous authors (e.g., Yang et al. 2012).

The above is not the only way to formally write the satellite CSMF; it can be written in a way that instead of implying knowledge of the change of \( m_s \) from accretion to observation implies only knowledge of the change of the subhalo CMF between these two epochs. Let us consider the distribution function, \( P_{\text{acc}}(m_{\text{acc}} | m_{\text{sub}} | z) \), given the probability that halos accreted at epoch \( z \) evolve, on average, to the observed (present-day) subhalos \( m_{\text{sub}} \), and the probability distribution function of these subhalos of hosting a galaxy of mass \( m_s \), \( P_{\text{sat}}(m_s | m_{\text{sub}} | z) \). In this case, the satellite CSMF (Equation (2)) is written as

\[
\Phi_s(m_s|M_h) = \int \int P_{\text{sat}}(m_s | m_{\text{sub}} | z) P_{\text{acc}}(m_{\text{acc}} | m_{\text{sub}} | z) \times \Phi(m_{\text{acc}} | M_h, z) dm_{\text{sub}} dm_{\text{acc}} dz.
\]  

and therefore the satellite GSMF, Equation (4), is given by

\[
\phi_{\text{sat}}(m_s) = \int \int P_{\text{sat}}(m_s | m_{\text{sub}} | z) P_{\text{acc}}(m_{\text{acc}} | m_{\text{sub}} | z) \times \phi_{\text{sub}}(m_{\text{acc}} | z) dm_{\text{sub}} dm_{\text{acc}} dz.
\]  

Since the \( m_{\text{acc}} \) subHMF would evolve into the \( m_{\text{obs}} \) subHMF, we write

\[
\phi_{\text{sub}}(m_{\text{obs}} | z) = \int \int P_{\text{acc}}(m_{\text{sub}} | m_{\text{acc}} | z) \phi_{\text{sub}}(m_{\text{acc}} | z) dm_{\text{sub}} dz.
\]  

This last equation is the abundance matching of accreted subhalos to present-day subhalos. Therefore,

\[
\phi_{\text{sat}}(m_s) = \int P_{\text{sat}}(m_s | m_{\text{sub}} | z) \phi_{\text{sub}}(m_{\text{obs}} | z) dm_{\text{sub}}.
\]  

This equation is nothing but abundance matching satellite galaxies to subhalos at the time they are observed. Hence, the reason that the satellite GSMF matches the subHMF in a more direct way for subhalo masses defined at the observation time (Equation (16)) than for those defined at the accretion time (Equation (12)) is that in the latter case the unknown \( P(m_s | m_{\text{acc}}, z) \) and \( P(m_{\text{acc}} | m_{\text{sub}}, z) \) “evolutionary” functions have to be introduced. However, we acknowledge that for the former case, our ignorance on the scatter around the SSMR is also a potential source of uncertainty. All our calculations are under the assumption that this scatter is the same as the scatter of the central SHMR. In any case, even if these scatters are different, note that including scatter affects the stellar-to-(sub)halo mass relation only at its high-mass end, where on average satellites are expected to be accreted recently; hence, their SSMR and scatter are similar to those of centrals/halos.

4.2. On the Intrinsic Scatter in the SSMR

A possible source of systematic errors in our analysis is the assumption that the intrinsic scatter around the SSMR, \( \sigma_s \), is constant and equal to the scatter around the central SHMR. To probe the impact of this assumption, we repeated all our analyses, this time assuming \( \sigma_s = 0 \). When comparing the results using \( \sigma_s = 0 \) to those obtained based on \( \sigma_s = 0.173 \) dex, we find that they are consistent with each other; therefore, they are consistent with the satellite CSMFs and with the galaxy spatial clustering measured from the YMB09 catalog. In more detail, we find that the resulting CSMFs reproduce observations for \( \sigma_s = 0 \) slightly better than for \( \sigma_s = 0.173 \) dex, especially at the massive end. This is because when the intrinsic scatter is not taken into account (\( \sigma_s = 0 \)), the shape of the SSMRs steepens at the massive end (see also Behroozi et al. 2010). Consequently, for a given \( m_s \), the subhalo mass is larger, and the abundances of larger (sub)halos are lower in general than those of smaller halos. Therefore, the number density of satellites at the massive end is lower. However, the projected correlation functions remain almost the same because the probability of finding a massive satellite galaxy in host halos less massive than log \( M_h \approx 13 \) is very low. They do not contribute significantly to the mean total density of galaxies. Although better models are needed in order to give a realistic form for \( \sigma_s \), our main conclusions seem to be robust to variations in the adopted value for \( \sigma_s \).

4.3. Implications for Satellite/Subhalo Evolution

The local SSMRs obtained for both definitions of the subhalo mass, \( m_{\text{acc}} \) and \( m_{\text{sub}} \), are such that at halo masses smaller than \( (2-10) \times 10^{13} M_\odot \) and at a given galaxy stellar mass the corresponding subhalo mass is smaller on average than the halo mass of centrals (Figure 2). This difference increases the smaller the mass is, and much more for the subhalo mass defined at the
observed time (present-day). In the case of \( m_{\text{sub}}^{\text{acc}} \), the differences might be because the halo mass at the epoch at which it became a subhalo (accretion time) is smaller than its present-day counterpart at a given stellar mass and/or because the satellite stellar mass increased more quickly than the central one for a given halo mass. In fact, it is difficult to make any inference in this case because the abundance matching is between local galaxies and (sub)halos at different past epochs. In any case, the fact that the inferred mass relations for satellites and centrals when \( m_{\text{sub}}^{\text{acc}} \) is used are not too different suggests that the central galaxy–distinct halo mass relation does not change too much with time, at least since the epoch at which most of the subhalos were accreted.

When \( m_{\text{sub}}^{\text{obs}} \) is used, both abundances of satellites and subhalos are matched at the same epoch: the observation (present-day) time. In this case, the strong difference between the satellite and central mass relations can be interpreted mainly as the result of subhalo mass loss due to tidal stripping. Besides, the smaller the subhalo, the larger the mass loss on average. The different evolution in stellar mass between central and satellite galaxies could probably also play a role for the differences, but not as significant a role as the one related to halo and subhalo mass evolution.

From Figure 2 one sees that for a given \( m_\ast \), the \( m_{\text{sub}}^{\text{obs}} \) to \( m_{\text{sub}}^{\text{acc}} \) ratio is 0.35–0.40 for the smallest masses up to \( m_\ast \sim 2 \times 10^{11} M_\odot \). At larger masses, this ratio rapidly tends to 1. Therefore, the subhalos of satellite galaxies less massive than \( m_\ast \sim 2 \times 10^{11} M_\odot \) have lost, on average (for all host halo masses\(^4\)), 65%–60% of their masses since they were accreted. It should be noted that this is a rough approximation and the evolution of the stellar mass since the satellite was accreted should be taken into account, see Section 4.1. This above result shows us that the galaxy–(sub)halo connection for satellite galaxies is far from direct; present-day satellites of masses \( m_\ast \sim 7 \times 10^9 M_\odot \) and larger have formed in subhalos that, at the time they were accreted onto galaxy sized halos, were on average a factor 2.5–3 larger than at the present epoch. This has severe implications for studies aimed at constraining the ΛCDM scenario at the level of subhalo/satellite distributions.

For example, it has been discussed that seeding the subhalos in simulations of MW-like halos using an extrapolation to low masses of the SHMR obtained by means of the AMT predicts an MW dwarf spheroidal (dSph) luminosity function in agreement with the observed one. However, the circular velocities at their maxima (or their masses at the infall) of those subhalos associated with the dSphs are significantly larger than inferences corresponding to kinematical observations (Boylan-Kolchin et al. 2012).

In the right panel of Figure 2 we have plotted the extrapolation to low masses of our SSMRs, both for subhalo masses defined at the present day (red line) and at the infall time (blue line). The observational points in the panel are for MW satellites, whose subhalo masses were estimated at their truncation radii. Thus, if we assume that these masses are roughly equal to the present-day subhalo masses in the ΛCDM simulations, then the simulated subhalo masses, \( m_{\text{sub}}^{\text{obs}} \), are up to \( \sim 10-30 \) times larger than those associated with dSphs. If the comparison is done with the extrapolation of the average (or central) SHMR, then the differences increase by a factor of \( \sim 3 \) more (see also Figure 7 in Boylan-Kolchin et al. 2012).

\(^4\) The dependence of the satellite–subhalo mass loss on the host halo mass will be explored elsewhere.
for pairs separated by a distance \( r \pm dr/2 \). Here \( \langle N(N - 1)/2 \) is the total mean number of galaxy pairs within halos \( M_h \) following a pair distribution \( \lambda(r) dr \), and a mean number density \( n_g(M_h) \). The contribution to the total mean number of galaxy pairs from central–satellite pairs and satellite–satellite pairs is

\[
\frac{\langle N(N - 1) \rangle}{2} \lambda(r) dr = \langle N_e \rangle \langle N_s \rangle \lambda_{c,s}(r) dr + \frac{\langle N(N - 1) \rangle}{2} \lambda_{s,s}(r) dr. \quad (A3)
\]

As commonly assumed in HOD models, the number of central–satellite pairs follows the normalized mass density halo profile, taken to be of Navarro et al. (1997) shape. The number of satellite–satellite pairs is then related to the normalized density profile convolved with itself.

Halo profiles are defined in terms of the total mass and the concentration parameter. We use the relation between concentration parameter \( c_{\text{NFW}} \) and halo mass obtained by Muñoz-Cuartas et al. (2011) from fits to N-body simulations.

Based on results of high-resolution N-body (Kravtsov et al. 2004) and hydrodynamic simulations of galaxy formation (Zheng et al. 2005), we model the second moment of satellite galaxies, \( \langle N_e(N_e - 1) \rangle \), as a Poisson distribution with mean \( \langle N_e \rangle^2 = \langle N_s(N_s - 1) \rangle \).

We compute the two-halo term as

\[
\xi^{gg}_{2h}(r) = b_g^2 \xi^2(r) \xi_m(r), \quad (A4)
\]

where \( \xi_m(r) \) is the nonlinear matter correlation function (Smith et al. 2003), \( \xi(r) \) is the scale dependence of dark matter halo bias (Tinker et al. 2005), and

\[
b_g = \frac{1}{n_g} \int_0^\infty b(M_h)\langle N > M_s | M_h \rangle \phi_h(M_h) dM_h \quad (A5)
\]

is the galaxy bias with \( b(M_h) \) the halo bias function (Sheth et al. 2001).

Once we have calculated \( \xi_{gg}(r) \), we relate it to the projected correlation function, \( w_p(r_p) \), integration over the line of sight,

\[
w_p(r_p) = 2 \int_0^\infty \xi_{gg}(\sqrt{r_p^2 + x^2}) dx. \quad (A6)
\]
