(Dated: September 1, 2004)

We present a theoretical method to determine the multipartite entanglement between different partitions of multimode, fully or partially symmetric Gaussian states of continuous variable systems. For such states, we determine the exact expression of the logarithmic negativity and show that it coincides with that of equivalent two–mode Gaussian states. Exploiting this reduction, we demonstrate the scaling of the multipartite entanglement with the number of modes and its reliable experimental estimate by direct measurements of the global and local purities.

PACS numbers: 03.67.-a, 03.67.Mn, 03.65.Ud

The full understanding of the structure of multipartite quantum entanglement is a major scope in quantum information theory that is yet to be achieved. At the experimental level, it would be crucial to devise effective strategies to conveniently distribute the entanglement between different parties, depending on the needs of the addressed information protocol. Concerning the theory, the conditions of separability for generic bipartitions of Gaussian states of continuous variable (CV) systems have been derived and analysed [1, 2, 3]. However, the quantification and scaling of entanglement for arbitrary states of multipartite systems remains in general a formidable task [4]. In this work, we present a theoretical scheme to exactly determine the multipartite entanglement of generic Gaussian symmetric states (pure or mixed) of CV systems.

elements and completely characterize Gaussian states by the

The CM \( \sigma \) one has simply \( \mu = 1/\sqrt{\det \sigma} \). For a Gaussian state with CM \( \sigma \) one

determine the exact expression of the logarithmic negativity and show that it coincides with that of equivalent two–mode Gaussian states. Exploiting this reduction, we demonstrate the scaling of the multipartite entanglement with the number of modes and its reliable experimental estimate by direct measurements of the global and local purities.

\begin{equation}
\sigma_{\beta} = \begin{pmatrix} \beta & \varepsilon & \cdots & \varepsilon \\ \varepsilon & \beta & \\
\vdots & \varepsilon & \ddots & \varepsilon \\ \varepsilon & \cdots & \varepsilon & \beta \end{pmatrix},
\end{equation}

where \( \beta \) and \( \varepsilon \) are 2 \times 2 submatrices. Due to the symmetry of such a state, \( \beta \) and \( \varepsilon \) can be put by means of local (single-mode) symplectic operations in the form \( \beta = \text{diag}(b, b) \), \( \varepsilon = \text{diag}(e_1, e_2) \). The symplectic spectrum \( \Sigma_{\beta} \) of \( \sigma_{\beta} \) has then the structure (see the Appendix)

\begin{equation}
\Sigma_{\beta} = \{ \nu_{-}, \ldots, \nu_{-}, \nu_{+/(N)} \},
\end{equation}

where the \( \beta \) and \( \varepsilon \) are 2 \times 2 submatrices. Due to the symmetry of such a state, \( \beta \) and \( \varepsilon \) can be put by means of local (single-mode) symplectic operations in the form \( \beta = \text{diag}(b, b) \), \( \varepsilon = \text{diag}(e_1, e_2) \). The symplectic spectrum \( \Sigma_{\beta} \) of \( \sigma_{\beta} \) has then the structure (see the Appendix)

\begin{equation}
\Sigma_{\beta} = \{ \nu_{-}, \ldots, \nu_{-}, \nu_{+/(N)} \},
\end{equation}

where the \( \beta \) and \( \varepsilon \) are 2 \times 2 submatrices. Due to the symmetry of such a state, \( \beta \) and \( \varepsilon \) can be put by means of local (single-mode) symplectic operations in the form \( \beta = \text{diag}(b, b) \), \( \varepsilon = \text{diag}(e_1, e_2) \). The symplectic spectrum \( \Sigma_{\beta} \) of \( \sigma_{\beta} \) has then the structure (see the Appendix)

\begin{equation}
\Sigma_{\beta} = \{ \nu_{-}, \ldots, \nu_{-}, \nu_{+/(N)} \},
\end{equation}

The \( (N-1) \)-degenerate eigenvalue \( \nu_{-} \) is independent of \( N \), while \( \nu_{+/(N)} \) can be expressed as a function of the purity \( \mu_{\beta} \equiv (\det \beta)^{-1/2} \) of the single–mode reduced state
and of the symplectic spectrum of the two-mode block $\sigma_{\beta^2}$, 

$$\Sigma_{\beta^2} = \{\nu_-, \nu_+ \equiv \nu_{+(2)}\}$$

$$\nu^2_\pm(N) = -\frac{N(N-2)}{\mu^2_\beta} + \frac{(N-1)}{2} \left( N \nu^2_\pm + (N-2)\mu^2_\beta \right) . \quad (3)$$

The global purity of the fully symmetric state is

$$\mu_{\beta N} \equiv (\text{Det } \sigma_{\beta N})^{-1/2} = (\nu_{N-1}^{-1} \nu_{+(N)})^{-1} , \quad (4)$$

and, through Eq. (3), can be directly linked to the one- and two-mode parameters. In particular, the symplectic eigenvalues $\nu_\mp$ are determined in terms of the two $Sp(4,\mathbb{R})$ invariants $\mu_{\beta^2}$ and $\Delta_{\beta^2}$ by the relation \[2\nu_\mp^2 = \Delta_{\beta^2} \mp \sqrt{\Delta_{\beta^2}^2 - 4/\mu_{\beta^2}^2} .\]

Next, we consider the $(N+1)$-mode Gaussian states constituted by generic single-mode states with CM $\alpha$ and fully symmetric $N$-mode states with CM $\sigma_{\beta N}$ of the form \[\sigma_{\beta N} \equiv \text{Diag}(\gamma_1, \ldots, \gamma_N) \equiv \text{Diag}(\gamma_1, \ldots, \gamma_N) . \quad (5)\]

We will now show that the properties of mixedness and entanglement of these states are determined by a suitable, limited set of global and local invariants under symplectic (unitary) operations. Let us introduce the purity $\mu_{\alpha} = (\text{Det } \alpha)^{-1/2}$ of the single-mode party, the global purity $\mu_{\sigma} = (\text{Det } \sigma)^{-1/2}$ of the state \[\sigma_{\beta N} = \text{Diag}(\gamma_1, \ldots, \gamma_N) \equiv \text{Diag}(\gamma_1, \ldots, \gamma_N) , \quad (6)\]

$$\Delta_{\alpha N} \equiv \text{Det } \alpha + 2N\text{Det } \gamma , \quad (6)$$

$$\Delta_{\beta N} \equiv N(\text{Det } \beta + (N-1)\text{Det } \varepsilon) . \quad (7)$$

We are now in the position to characterize and quantify the bipartite entanglement between the single mode $\alpha$ and the $N$-mode block $\sigma_{\beta N}$, the multipartite entanglement between all the $N+1$ modes, and to provide an operational scheme for their experimental determination in terms of measurements of the global and local purities. To proceed, we must evaluate the logarithmic negativity by determining the partially transposed CM $\tilde{\sigma}$, with respect to the partition $\alpha | \beta N$), which is obtained by flipping the sign of $\text{Det } \gamma$. Mixedness and entanglement are encoded respectively in the symplectic spectrum of $\sigma$, and of $\tilde{\sigma}$. It is worth noting that, of the previously introduced parameters, only $\Delta_{\alpha N}$ is affected by the operation of partial transposition: $\Delta_{\alpha N} \rightarrow \tilde{\Delta}_{\alpha N}$, with

$$\tilde{\Delta}_{\alpha N} = \text{Det } \alpha - 2N\text{Det } \gamma \equiv -\Delta_{\alpha N} + 2/\mu_{\alpha}^2 . \quad (8)$$

The symplectic spectrum $\Sigma = \{n_i\} (i = 1, \ldots, N+1)$ of the CM $\sigma_{\beta N}$ is of the form (Appendix)

$$\Sigma = \{\nu_-, \ldots, \nu_-, n_-, n_+\} , \quad (9)$$

where $\nu_-$ is the lowest symplectic eigenvalue of the reduced two-mode state $\sigma_{\beta^2}$. The eigenvalues $\nu_{\mp}$ can be evaluated observing that Eqs. (4,7,9) impose the identity $\Delta_{\alpha N} = \Delta_{\alpha N} + 2N(\nu_{N-1}^{-1} + \nu_{N-1}^{-1} \mu_{\beta N})^2$ which can be used to obtain

$$2\nu_{N-1}^2 = \Delta_{\alpha N} + 2N(\nu_{N-1}^{-1} \mu_{\beta N})^2 \mp \sqrt{(\Delta_{\alpha N} + 2N(\nu_{N-1}^{-1} \mu_{\beta N})^2)^2 - 4/\mu_{\alpha}^2 \mu_{\beta N}^2} . \quad (10)$$

Since partial transposition leaves the $N$-mode symmetric block $\sigma_{\beta N}$ unchanged, the symplectic eigenvalues of $\tilde{\sigma}$ are again of the form $\Sigma = \{n_1\} = \{\nu_-, \ldots, \nu_-, \tilde{n}_-, \tilde{n}_+\}$, with $\tilde{n}_{\mp}$ defined as in Eq. (10), but with $\Delta_{\alpha N}$ replaced by $\tilde{\Delta}_{\alpha N}$ from Eq. (8). The logarithmic negativity $E_{eq[N]}^{\alpha[\beta N]}$, quantifying the bipartite entanglement between $\alpha$ and $\sigma_{\beta N}$, is determined only by those symplectic eigenvalues of $\tilde{\sigma}$ which satisfy $\tilde{n}_1 < 1$. Since $\nu_- \geq 1$ (because it belongs to the symplectic spectrum of $\sigma$), the entanglement is determined only by the eigenvalues $\tilde{n}_1$. On the other hand, the eigenvalues $\tilde{n}_\mp$ of Eq. (10) can be interpreted as the symplectic spectrum of an equivalent two-mode state of CM $\sigma_{\beta N}$ with global purity $\mu_{\sigma}$ and seralian $\Delta_{\tilde{\sigma}}$ given by

$$\mu_{\sigma} = \nu_{N-1}^{-1} \mu_{\alpha} , \quad \Delta_{\tilde{\sigma}} = \Delta_{\alpha N} + 2N(\nu_{N-1}^{-1} \mu_{\beta N})^2 - 2 \nu_{N-1}^{-1} \mu_{\sigma} . \quad (11)$$

The corresponding $\tilde{\Delta}_{eq}$ associated to the partially transposed CM $\tilde{\sigma}_{eq}$ reads then $\tilde{\Delta}_{eq} = -\tilde{\Delta}_{eq} + 2/\mu_{\alpha} + 2/\mu_{\beta N}^2$. By comparison with the expression $\Delta = -\Delta + 2/\mu_{\alpha} + 2/\mu_{\beta N}^2$, holding for a generic two-mode state with local purities $\mu_{1}$ and $\mu_{2}$, one determines the local purities of the equivalent two-mode state $e_{\beta N}$:

$$\mu_{1}^{eq} = \mu_{\alpha} , \quad \mu_{2}^{eq} = \nu_{N-1}^{-1} \mu_{\beta N} . \quad (12)$$

The two global invariants Eq. (11) and the two local invariants Eq. (10) determine uniquely the entanglement of the two-mode Gaussian state with CM $\sigma_{\beta N}$. In particular, it is immediate to see that the symplectic eigenvalues of the partially transposed CM $\tilde{\sigma}_{eq}$ coincide with $\tilde{n}_{\mp}$, so that we obtain the crucial result that the logarithmic negativity of the equivalent two-mode state coincides with the logarithmic negativity $E_{eq[N]}^{\alpha[\beta N]}$ of the $(N+1)$-mode state. Explicitly, one has:

$$E_{eq[N]}^{\alpha[\beta N]} = \max\{0, -\log \tilde{n}_-\} , \quad (13)$$

with $2\tilde{n}_- = \tilde{\Delta}_{eq} = \sqrt{\tilde{\Delta}_{eq}^2 - 4/\mu_{\sigma}^2 \mu_{\beta N}^2}$. Indeed, only the smallest symplectic eigenvalue $\tilde{n}_-$ enters in the determination of the multimode entanglement, since $\tilde{n}_+ > 1$ for two-mode states $\tilde{\sigma}$. The $1 \times N$ entanglement is completely quantified by measuring the two local purities $\mu_{1}$ and $\mu_{\beta N}$, the global purity $\mu_{\sigma}$, the symplectic eigenvalue $\nu_-$, and $\text{Det } \gamma$ (which together with $\mu_{\alpha}$ determines $\Delta_{\alpha N}$). The experimental determination of these five quantities requires the full homodyne reconstruction of the $(N+1)$-mode CM Eq. (4). On the other hand, the study
of the entanglement of two-mode Gaussian states has shown that a reliable quantitative estimate of the logarithmic negativity, yielding exact (and very narrow) lower and upper bounds on the entanglement, can be obtained by simply measuring the global and local purities of the state \[ \gamma. \] In the present instance, this fact implies that a reliable estimate of the \( 1 \times N \) entanglement does not require the knowledge of the correlation matrix \( \gamma \), while the remaining few quantities (the three purities and the eigenvalue \( \nu_+ \)) can be measured even without homodyning by direct single–photon detections \[ |. \] Moreover, knowledge of these few quantities is also sufficient to determine the multimode, multipartite entanglement of the state \( \sigma \).

In fact, the fully symmetric \( N \)-mode block \( \sigma_{\beta N} \) can be again regarded as a state describing a mode with CM \( \beta \) coupled with a fully symmetric \((N-1)\)-mode block \( \sigma_{\beta N-1} \), and thus the \( 1 \times (N-1) \) entanglement within \( \sigma_{\beta N} \) can again be computed by constructing the corresponding equivalent two-mode state and evaluating its entanglement. This scaling procedure can be iterated to determine all the multimode entanglements existing between each mode and each fully symmetric \( K \)-mode sub-block \( \sigma_{\beta K} \) \((K = 1, \ldots, N)\). The \( 1 \times K \) entanglement between a single mode \( \alpha \) and any fully symmetric \( K \)-mode partition \( \sigma_{\beta K} \) of the \( \beta N \) can be determined in a similar way. A crucial feature of this scaling structure of the multipartite entanglement is that, at every step of the cascade, the \( 1 \times K \) entanglement is always equivalent to a \( 1 \times 1 \) entanglement, so that the quantum correlations between the different partitions of \( \sigma \) can be directly compared to each other: it is thus possible to establish a multimode entanglement hierarchy without any problem of ordering.

To illustrate the scaling structure of multipartite entanglement in CV systems let us consider a pure, \((N+1)\)-mode fully symmetric Gaussian state of the form of Eq. \[ \text{(1)}. \] Imposing the constraint of pure state \((\mu = 1 \Leftrightarrow \nu_- = \nu_{\perp(N+1)} = 1)\), one obtains \( e_i = [1 + b^2(1-1) - N - (1)^2(1) + (1)^2]2b/N \). Such a state belongs to the class of CV GHZ–type states discussed in Ref. \[ \text{(3)}. \] These multipartite entangled states are the outputs of a sequence of \( N \) beam splitters with \( N + 1 \) single-mode squeezed inputs \[ \text{(3)}. \] In the limit of infinite squeezing, these states reduce to the simultaneous eigenstates of the relative positions and the total momentum, which define the proper GHZ states of CV systems \[ \text{(3)}. \] The CM \( \sigma_{\beta N+1}^{\text{GHZ}} \) of this class of pure states, for a given number of modes, depends only on the parameter \( b \equiv 1/\mu_\beta \geq 1 \), which is an increasing function of the single-mode squeezing. Correlations between the modes are induced according to the above expression for the covariances \( e_i \). Exploiting our previous analysis, we can compute the entanglement between a single mode with reduced CM \( \beta \) and any \( K \)-mode partition of the remaining modes \((1 \leq K \leq N)\), by determining the equivalent two-mode CM \( \sigma_{\beta K}^{\text{eq}} \). The \( 1 \times \) \( K \) entanglement quantified by the logarithmic negativity \( E_{\beta K}^{\gamma} \) is determined by the smallest symplectic eigenvalue \( \tilde{\gamma}_{(K,N)} \) of the partially transposed CM \( \sigma_{\beta K}^{\text{eq}} \).

\[ \sigma_{\beta K}^{\text{GHZ}} \]. For any nonzero squeezing \((i.e. \ b > 1)\) one has that \( \tilde{\gamma}_{(K,N)} < 1 \), meaning that the state exhibits genuine multipartite entanglement: each mode is entangled with any other \( K \)-mode block, as first remarked in Ref. \[ \text{(3)}. \] Further, the genuine multipartite nature of the entanglement can be precisely quantified by observing that \( E_{N}^{\beta K} \geq E_{N}^{\beta K-1} \), as shown in Fig. \[ \text{1}. \] The \( 1 \times 1 \) entanglement between two modes is weaker than the \( 1 \times 2 \) one between a mode and other two modes, which is in turn weaker than the \( 1 \times K \) one, and so on with increasing \( K \) in this typical cascade structure. From an operational point of view, the signature of genuine multipartite entanglement is revealed by the fact that performing e.g. a local measurement on a single mode will affect all the other \( N \) modes. This means that the quantum correlations contained in the state with CM \( \sigma_{\beta N+1}^{\text{GHZ}} \) can be fully recovered only when considering the \( 1 \times N \) partition. In particular, the pure-state \( 1 \times N \) logarithmic negativity is, as expected, independent of \( N \), being a simple monotonic function of the entropy of entanglement \( E_V \) (defined as the von Neumann entropy of the reduced single-mode state with CM \( \beta \)). It is worth noting that, in the limit of infinite squeezing \((b \to \infty)\), only the \( 1 \times N \) entanglement diverges while all the other \( 1 \times K \) quantum correlations remain finite (see Fig. \[ \text{1}. \] Namely, \( E_{N}^{\beta K} \to E_{N}^{\beta K} \) \((b \to \infty)\) \(- (1/2) \log[1 - 4K/(N(K+1) - K(K-3))]\), which cannot exceed \( \sqrt{5} \approx 0.8 \) for any \( N \) and any \( K < N \). At fixed squeezing, the scaling with \( N \) of the \( 1 \times (N-1) \) entanglement compared to the \( 1 \times 1 \) entanglement is shown in Fig. \[ \text{1}. \] (we recall that the \( 1 \times N \) entanglement is independent on \( N \)). Notice how, with increasing number of modes, the multipartite entanglement increases to the detriment of the two-mode one which becomes distributed between all the modes. We remark that this scaling occurs in any Gaussian states, either fully or partially symmetric, pure or mixed. For instance, this is the case for a single–mode squeezed state coupled with a \( N \)-mode symmetric thermal squeezed state. The simplest example of a mixed state with genuine multipartite entanglement is obtained from \( \sigma_{\beta N+1}^{\text{GHZ}} \) by tracing out some of the modes. Fig. \[ \text{1}. \] can then also be seen as a demonstration of the scaling in such a \( N \)-mode mixed state, where the \( 1 \times (N-1) \) en-
entanglement is the strongest one. Thus, with increasing \( N \), the global mixedness can limit but not destroy the genuine multipartite entanglement between all the modes. This entanglement is experimentally accessible by all-optical means \(^3\) and it also allows for a reliable (i.e., with fidelity \( F > 1/2 \)) quantum teleportation between any two parties \(^1\). Therefore, the quantification of multipartite entanglement by measurements of purity, which, as we have already remarked, can be experimentally implemented even without homodyning, leads to an accurate estimate of the multi-party teleportation efficiency and to direct control on the transfer of quantum information.

In conclusion, we have shown that multipartite quantum correlations of Gaussian states of \( 1 \times N \) partitions under symmetry are endowed with a scaling structure that reduces the problem to the analysis of the entanglement of equivalent two-mode Gaussian states. Thanks to this reduction, it is possible to determine exactly the logarithmic negativity of the multimode states and to allow for a reliable experimental estimate of the multipartite entanglement by direct measurements of global and local purities, without the need for the full reconstruction of the covariance matrix. Our results apply to many cases of practical interest. For instance, the entire class of bisymmetric – i.e., invariant under the exchange of two given modes – three-mode Gaussian states \(^2\) has its multipartite entanglement completely quantified by the present analysis. The generalization of the present approach for the quantification of multipartite CV entanglement to states with weaker symmetry constraints and to \( M \times N \)-mode partitions (with \( M > 1 \)) awaits further study.

Financial support from INFN, INFN, and MIUR is acknowledged.

Appendix: Proof of the symplectic degeneracy. We prove here the multiplicity of the symplectic eigenvalue \( \nu_- \) for the CMs \( \sigma_{\beta N} \) and \( \sigma_\nu \) asserted in Eqs. (2) and (9). We first recall that, if \( \Sigma = \{\nu_1, \ldots, \nu_N\} \) is the symplectic spectrum of the CM \( \sigma \), then the \( 2N \) eigenvalues of the matrix \( i\Omega \sigma \) are given by the set \( \{ \mp \nu_i \} \). Let us focus next on the CM \( \sigma_{\beta 2} \): in the linear space on which the matrix \( i\Omega \sigma_{\beta 2} \) acts, the eigenvector \( \nu_- \) corresponding to the eigenvalue \( \nu_- \) reads \( \nu_- = (-i^{b-e_i}/\nu_-, -1, i^{b-e_i}/\nu_-)^T \). Due to the symmetry of \( \sigma_{\beta N} \), any \( 2N \)-dimensional vector \( v \) of the form \( v = (0, \ldots, 0, -i^{b-e_i}/\nu_-, -1, 0 \ldots, 0, i^{b-e_i}/\nu_-)^T \) (i.e., any vector obtained by taking \( \nu_- \) in a couple of modes \( ij \) and appending to it 0 elements for all the other modes) is an eigenvector of \( i\Omega \sigma_{\beta N} \) with eigenvalue \( \nu_- \). It is immediate to see that one can construct \( N-1 \) linear independent vectors of the above form, proving Eq. (2). Clearly, an analogous reasoning holds for the matrix \( \sigma_\nu \), proving Eq. (9).

\[\begin{align*}
\text{FIG. 2: Scaling as a function of } N \text{ of the } 1 \times 1 \text{ and of the } 1 \times (N-1) \\
\text{entanglement for a } (N+1)\text{-mode GHZ-type CV pure state } (b = 1.5).
\end{align*}\]
