In this report we present preliminary results about the tunneling problem for a magnetic Schrödinger operator. As a motivation we consider the 3-D time-dependent Schrödinger operator \( H(t) = -\hbar^2 \Delta + V + E(t) \cdot x \) where \( V \) is a radial potential and \( E(t) \) a circularly polarized field with uniform frequency \( \omega \). The quantum monodromy operator (QMO) that takes the system through a complete period \( T = 2\pi/\omega \), turns out to be unitarily equivalent to \( e^{iTPA(x, hD_x)/\hbar} \) where \( P_A(x, hD_x) \) identifies with a magnetic Schrödinger operator. When \( V \) is sufficiently confining, \( P_A(x, hD_x) \) presents a double magnetic well. Then we construct its semi-classical ground state and examine the splitting between its two first eigenvalues.

1 Introduction

The general motivation is to describe some (semi-classical) spectrum for the quantum monodromy operator (QMO) associated with a periodic time dependent self-adjoint \( N \)-body Schrödinger operator \( H(t) \) on \( L^2(\mathbb{R}^{3N}) \). Recall QMO is the unitary operator that evolves the physical system through one period. This spectrum is the same as for Floquet Hamiltonian \( \tilde{H} = D_t + H(t) \) on \( L^2(\mathbb{R}^{3N} \times \mathbb{T}) \), see e.g. [21]. Scattering theory for Floquet Hamiltonian leads to important properties, such as local decay (in time) for the probability density. Bound states are also of interest, e.g. regarding tunneling properties. A.Tip [23] has investigated the case where \( H(t) \) is the Hamiltonian for an atom with \( N \) particles of charge \( e_j \) and mass \( m_j \) (\( e_0 = N \) being the charge of the nucleus of mass \( m_0 \)) subject to the circularly polarized periodic electric field \( E_1(t) = (\sin \omega t, -\cos \omega t, 0) \in \mathbb{R}^3 \). Let also \( V \) (rotationally invariant in \( \mathbb{R}^{3N} \)) be the sum of all Coulomb potentials between the particles of charge \( e_j \). Neglecting spin effects, we have

\[
H_1(t) = \sum_{j=0}^{N-1} (2|m_j|)^{-1} p_j^2 + V(x) - \sum_{j=0}^{N-1} e_j x_j \cdot E_1(t)
\]

Time-evolution \( U_1(t, s) \) corresponding to \( H_1(t) \) is well defined, and QMO is \( U_1(T + s, s) \) (independent of \( s \in \mathbb{R} \)). An equivalent formulation can be given in terms of

\[
H_2(t) = \sum_{j=0}^{N-1} (2|m_j|)^{-1} (p_j - e_j A_2(t)) + V(x)
\]

with \( E_1(t) = -\partial_t A_2(t) \), and the corresponding time-evolutions \( U_2(t, s) \). \( j = 1, 2 \) are related by a unitary operator \( X(t) \). One of the main observations in [23] is that the group of unitary operators \( R(t) = e^{i\omega sL_3} \), \( L_3 \) being the vertical component of the angular momentum (tensor product over the \( N \) particles), takes \( A_2(t) \) into a constant magnetic potential \( A_0 = (\frac{1}{\omega}, 0, 0) \), i.e.

\[
R(t)H_2(t)R(t)^{-1} = \sum_j (2|m_j|)^{-1} (p_j - e_j A_0)^2 + V(x)
\]

and

\[
U_2(t, s) = e^{-i\omega sL_3} P_A e^{i\omega sL_3}
\]

where \( P_A \) is the time-independent self-adjoint operator

\[
P_A = \sum_{j=0}^{N-1} (2|m_j|)^{-1} (p_j - e_j A_0)^2 + V(x) - \omega L_3
\]

Quantum monodromy operator \( U_2(s + T, s) \) over the period \( T = 2\pi/\omega \), is of the form

\[
U_2(s + T, s) = e^{-i\omega sL_3} e^{iTPA} e^{i\omega sL_3}
\]
This relates the (discrete) spectra of $U_2(s + T, s)$ and $P_A$ (either real spectrum or resonances), in the sense that if $E$ is an eigenvalue of $P_A$, then $F = e^{iTE}$ is an eigenvalue of $U_2(s + T, s)$. For simplicity we assume henceforth there is only one heavy nucleus and one electron $x \in \mathbb{R}^3$, and introduce a semi-classical parameter $h$ so that $L_3 = x_1 h D_{x_2} - 2 x_2 h D_{x_1}$, and $P_A$ on $L^2(\mathbb{R}^3)$ takes the form $P_A(x, h D_{x_2}) = (h D_{x_2} - \nu A_0)^2 + V(x) - \omega L_3$, where $\nu$ is a coupling constant. In case $V$ is Coulomb potential, the complex dilation theory of $P_A$ set up in [23] gives an insight into the resonant spectrum of $P_A$. Here we still assume $V$ to be rotation invariant, but allow for non Coulomb (confining) potentials, so that $P_A$ has discrete, real spectrum.

2 Hamiltonians

The classical Hamiltonian is

$$p_A(x, \xi) = (\xi_1 - \frac{\nu}{\omega})^2 + \xi_2^2 + \frac{1}{\omega^2} V(|x|) - \omega (x_1 \xi_2 - x_2 \xi_1),$$

and we may rewrite $P_A$ as a magnetic Schrödinger operator. Namely, after the affine change of coordinates $x = \frac{2}{\omega} y + (0, \frac{2\nu}{\omega^2}, 0)$, and the substitution $W(y) = \frac{1}{2\omega^2} [V(|x(y)|) - \frac{1}{\omega^2} (y_1^2 + y_2^2)]$, we get

$$p_A(x, \xi) = \sqrt{\omega^2} p_A'(y, \eta) + \frac{\nu^2}{\omega^2},$$

where

$$p_A'(y, \eta) = (\eta_1 + \frac{2\nu^2}{\omega^2} y_2)^2 + (\eta_2 - \frac{2\nu^2}{\omega^2} y_1)^2 + \eta_3^2 + W(y) = (\eta - \omega A(y))^2 + W(y)$$

Note that the corresponding operator $P_A'(y, h D_{y_3})$ commutes with symmetry $y_3 \mapsto -y_3$. General spectral properties of magnetic Schrödinger operators are well-known, see e.g. [47], in particular when $W(y) \to +\infty$ as $y \to \infty$, $P_A'(y, h D_{y_3})$ has only discrete spectrum.

Discrete semi-classical spectrum of $P_A$ near some energy level $E$ is generally associated with local minima of the Hamiltonian. Among these minima it is easy to find those which are the critical points of $r \mapsto V(r)$, namely

$$\rho_0^\pm = (x_0, \xi_0)^\pm = ((0, 2\nu \omega^{-2}, \pm \sqrt{r_0^2 - 4\nu^2 \omega^{-4}}), 0)$$

with $V(r_0) = E - \omega^2 \nu^{-2}$. We will write as well $\rho_0^\pm = (y_0^\pm, y_0^\pm) = (y_0^0, 0)$ in the new coordinates $y$.

So the $y$-projection of the critical points $y_0^\pm$ of $p_A'(y, \eta)$ are located on the $y_3$-axis, symmetric with respect to the $(y_1, y_2)$ plane. At such a critical point, $\eta_0^\pm = 0$.

For a suitable choice of parameters $(r_0, V'(r_0), \omega, \nu)$, it may happen that $\rho_0^\pm$ is an elliptic point even if $r_0$ is not a minimum of $V$. However, to meet hypotheses of [19], we assume that $E$ is the bottom of the spectrum of $P_A$, and thus $r_0$ is a global minimum of $V$. To avoid multiple tunneling, we assume also that there is no other critical points of $P_A$ than $\rho_0^\pm$ at energy $E$.

Such elliptic fixed points $\rho_0^\pm$ of Hamiltonian $P_A$, will be called the magnetic microlocal wells. We consider Dirichlet realization $P^M_A(x, h D_{x_2})$ localized in some (large enough) neighborhoods $M \subset \mathbb{R}^3$ of $x_0^\pm$ (by symmetry $P^M_A(x, h D_{x_2})$ are unitarily equivalent) and study their semi-classical spectrum in a $h$-neighborhood of $E$, see [9]. Note that the spectral parameters for $P^M_A$ and $P^M_{A'}$ are related as follows:

$$P^M_A(x, h D_{x_2}) u_\pm(x) = (E + \lambda A(h)) u_\pm(x)$$

$$\iff P^M_{A'}(y, h D_{y_3}) u_\pm'(y) = (E' + \lambda'(h)) u_\pm'(y)$$

where $E' = \frac{4\nu^2}{\omega^2} V(r_0)$, $\lambda A(h) = \frac{4\nu^2}{\omega^2} \lambda A(h)$, and $u_\pm'(y) = u_\pm(x)$ we will denote for short again by $u_\pm(y)$. We know that the first eigenvalue $\lambda A(h)$ of $P^M_{A'}(x, h D_{x_2}) - E$ is non degenerate. By tunneling, this will gives raise to splitted eigenvalues $E_0(h) < E_1(h)$ for $P_A(x, h D_{x_2})$ exponentially close to $\lambda A(h)$. Thus our main goal consists in solving the rather standard problems: (1) Find semi-classical asymptotics of $\lambda A(h)$, $h \to 0$. (2) Estimate the splitting $E_1(h) - E_0(h)$ (tunneling between $\rho_0^\pm$). Point (1) results directly from the general microlocal arguments of [19] near $\rho_0^\pm$ applied to $P_A$, that we recall here. Point (2) relies more specifically on the fact that $P_A$ (or $P_A'$) is a magnetic Schrödinger operator. Both use complexification of time $t \mapsto it$ for Hamilton equations in the “classically forbidden region”.

3 Microlocal approach: WKB expansions near the microlocal magnetic well.

We work with $P_A$ rather than the rescaled operator $P_A'$, and since our constructions will hold in a small neighborhood of $x_0 = x_0^\pm$, $x_0 \in M = M^+$ say, we shall write sometimes $P_A$ instead of $P^M_A(x, h D_{x_2})$. At an elliptic fixed point Floquet exponents, i.e. eigenvalues of the fundamental matrix $F_{PA} = \mathcal{J} \text{Hess} p_A(\rho_0^\pm)$, are purely imaginary. Their square $\mu^2$ are the roots of a 3:rd degree polynomial with real coefficients. It turns out that we
can find an open set of parameters $(r_0, V''(r_0), \omega, \nu)$ such that $r_0 \omega^2 \nu^{-1} \geq 2$ and $\mu_1^2 < \mu_2^2 < \mu_3^2 < 0$. When these conditions are met, applying a linear canonical transformation $\kappa_A$, and setting the reference energy to $E' = 0$ to simplify notations, which amounts to set $V(r_0) = 0$, $p_A$ takes the form, with $\mu_j = i\mu_j$, $\mu_j > 0$

$$p_A(x, \xi) = \sum_{j=1}^{3} \mu_j (x_j + \xi_j^2) / 2 + O(|x, \xi|^3)$$

in local coordinates $(x, \xi)$ vanishing at $\rho_0^+$ (but not the same as the original coordinates of the problem). It is important to note that, although $\kappa_A$ changes drastically the geometry of the phase-space, we still get informations on $u_A(y)$, see [12].

Remark 5.2 and below. Namely, $\kappa_A$ does not generate additional caustics in the region of interest.

Examine first WKB constructions and decay properties of the normalized quasi-mode associated with $\lambda_A(h)$ by microlocal techniques and the method of complex deformations [9], [10], [7], [17]. We follow here [10].

Consider the global FBI transform (with $c(h)$ a normalization constant)

$$Tu(x, \xi; h) = c(h) \int_{\mathbb{R}^3} e^{i(x-y)/h - (x-y)^2/2h} u(y) dy$$

that maps isometrically $L^2(\mathbb{R}^3)$ into $L^2(\mathbb{R}^n)$. It is associated with the transformation $\kappa_T : T^* \mathbb{R}^3 \to \Lambda = \{ (\zeta = i \text{Im }z), (x, \xi) \mapsto (z, \zeta) = (x - i\xi, -i\xi) \}$, such that $-\text{Im}(dz \wedge d\zeta) = dx \wedge d\xi$, $\text{Re}(dz \wedge d\zeta) = 0$ on $0$. The pluri-subharmonic (p.s.h) weight defining $\Lambda$, is $-\phi_0(z, \zeta) = (\text{Im }z)^2$, namely $\Lambda = \{ \zeta = \frac{\phi_0}{2h^2} \}$. Transformation $T_A$ intertwines $P_A$ with $\tilde{P}_A(x, \xi, hD_x, hD_\xi)$ whose Weyl symbol is given by $\tilde{p}_A(x, \xi, x', \xi'; x', \xi') = p_A^2(x - \xi, x', \xi')$, so that the eigenvalue equation becomes, with $u_T = Tu$ and $u = u_T$ as in (??)

$$(\tilde{P}_A(x, \xi, hD_x, hD_\xi) - \lambda_A(h))^j u_T(x, \xi; h) \sim 0$$

which will solve by WKB method, by looking for $u_T$ of the form $u_T(z, h) \sim e^{-\xi^2/2h - \varphi(z)/h} a(z; h)$. The reduced operator $\Psi(x, \xi, hD_x, hD_\xi) = e^{\xi^2/2h + \varphi(z)/h} \tilde{P}_A(x, \xi, hD_x, hD_\xi) e^{-\xi^2/2h - \varphi(z)/h}$ acting (formally) on symbols $a(z; h)$ is indeed a $h$-PDO $\Psi(z, hD_z; h)$ with symbol $\sigma_{\Psi}(z, \zeta; h) \sim \sigma_0(z, \zeta) + h\sigma_1(z, \zeta) + \cdots$, and $\sigma_0(z, \zeta) \sim -p_A(z - \zeta, \zeta')$.

**Remark 1.** We can also use the standard unitary Bargman transform [22] $T_0 : L^2(\mathbb{R}^3) \to H_0(\mathbb{C}^3)$, space of holomorphic functions square integrable with respect to the weight $\Psi(z) = |z|^2/4$. It is somewhat more natural in this context, but we found it convenient to stick to notations of [17], [18].

Performing another "absolute" metaplectic complex transformation $T_2$ (independent of all parameters), associated with a complex canonical transformation $\kappa_2$, we can arrange so that $\sigma_0$ has the quadratic approximation $\sigma_0(\zeta, \zeta) = \sum_{j=1}^{\infty} 2\mu_j \zeta_j \zeta_j$ near the magnetic microlocal well. We still denote by $u_T$ the corresponding quasi-mode. In fact $T_2$ could be avoided if we replace $T$ by $T_0$.

We solve Hamilton-Jacobi (HJ) equation

$$\sigma_0(z, \partial_z \varphi_0(z) = 0 \text{ by } \varphi_0(z) = \frac{1}{4} z^2.$$ 

This gives the complex "outgoing" Lagrangian manifold $\Lambda_\pm = \{ \zeta = \partial_z \varphi_0(z) \}$, and also the "incoming" one $\Lambda_\pm = \{ \zeta = -\partial_z \varphi_0(z) \}$. By the stable-unstable manifold Theorem this carries to $\sigma_0(z, \zeta)$, thus we can solve HJ equation with holomorphic phase function $\varphi(z) = \varphi_0(z) + O(|z|^3)$ defining $\Lambda_\pm$. Continuing this way, we can also solve the transport equations with an analytic symbol $a(z; h)$. Altogether we get a WKB solution of

$$(\Psi(z, hD_z; h) - \lambda_A(h))a(z; h) \sim 0 \text{ microlocally near } \rho_0 = \rho_0^+,$$

such that

$$u_T(z, h) \sim e^{-\xi^2/2h - \varphi(z)/h} a(z; h)$$

Here $\sim$ means modulo a remainder term $O(e^{-1/Ch})$. Applying classical variational principles, this is justified by Agmon type estimates, which say how close the microlocal solution approaches the actual eigenfunction. To this end, we use the method of non characteristic deformations. Namely in some neighborhood $\Omega(0, 0)$ where microlocal solution (??) holds (i.e. before the occurrence of focal points on $\Lambda_\pm$) there is a deformation of $-\phi_0$ to a family of p.s.h. weights $-\phi_t(z, \zeta)$, such that the R-Lagrangian manifold $\Lambda_t = \exp tH_\rho(\Lambda)$ is transverse to $\{ z = 0 \}$ at $(0, 0)$, and hence of the form $\zeta = \frac{\phi_0}{2h^2}$. We check that $\phi_t(z, \zeta) \to 2 \text{Re } \varphi(z)$ as $t \to \infty$. Moreover $\sigma_0$ remains elliptic outside $(0, 0)$ along these deformations, in the sense $-\sigma_0(\zeta, \zeta) \Lambda_\pm \geq \text{Const.} |z|^2 + |\zeta|^2$ for all $t$, and $\phi_t$ satisfies the eikonal equation $\partial_t \phi_t(z, \zeta) = -2\sigma_0(z, \partial_t \phi_t)$. We then modify $\phi_t$ to another weight $\psi_t$ such that $\psi_t < 2 \text{Re } \varphi_t$ near $\partial \Omega$, where WKB constructions of type (??) fail to exist, and get the following Agmon estimate: If $u$ is the 1st normalized eigenfunction of $P^A_\Lambda$ then for any compact set $K \subset \Omega$, there exists $\varepsilon > 0$ and $h_\varepsilon > 0$, such that uniformly for $z = x - i\xi \in K$,.
0 < h < h_{\varepsilon} we have
\[ e^{\xi^2/2h}\varphi(x-i\xi/h)(Tu_x(x,\xi;h) - u_T(x,\xi;h)) = O(e^{-\varepsilon/h}) \] (8)
Altogether, this gives the asymptotics for the first eigenvalue \( \lambda_A(h) \) for \( P_A^M(x, hD_x) \)
\[ \lambda_A(h) = h \text{Tr}^+(F_{PA}) + O(h^2) \] (9)
where \( \text{Tr}^+(F_{PA}) = \sum_{j=1}^{3} \mu_j \). This gives also the asymptotics of \( Tu_+ \) in \( \Omega \subset M \).

The main drawback is the poor control of the neighborhood of \( x_0 \) where this asymptotics holds for \( u = T^{-1}u_T \) (left inverse), because \( \kappa_A \) is not merely implied by a change of variables in the x-space. Nevertheless since \( \kappa_A^{-1}(\Lambda_+), \Lambda_+ = \{ \zeta = i\tilde{\nu}_2(x) \} \) is a strictly positive Lagrangian manifold at \((0,0)\) (also after applying \( \kappa_A \)), the same holds for \( \kappa_A^{-1} \circ \kappa^{-1}(\Lambda_+) \) (in the initial canonical variables), and so \( \Lambda_+ \) has no focal points near \( p_0 \). So Agmon estimate (??) again justifies the asymptotics of \( u \) of \( P_A^M(x, hD_x) \) in some (real) neighborhood \( \Omega_R \) of \( x_0 \).

Of course by symmetry \( y_3 \mapsto -y_3 \) everything carries to \( M^- \). To proceed we need to extend WKB constructions, when \( \omega' \) is small enough, near minimal geodesics for Agmon metric associated with the Hamiltonian without a magnetic field. 

### 4 Geometry and Quantization of Magnetic Hamiltonians

We work here with the rescaled operator \( P_A^M(y, hD_y) = (P_A^M)^M(y, hD_y) \) localized in \( M = M^+ \). In Classical Mechanics the generalized momentum \( \eta \) of a particle is related to its velocity by \( v = \eta - A(y) \). The magnetic symplectic 2-form is
\[ \sigma_A = dv \wedge dy = d\eta \wedge dy + dA(y) = \sigma + dA(y) \]
Consider first the kinetic term \( K_0(y, \eta) = |v|^2 = (\eta - A(y))^2 \). We know [12, 20] that if \( dA(y) \neq 0 \), then \( \Sigma = \{ K_0 = 0 \} = \{ dK_0 = 0 \} \) is a 3-D submanifold of \( T^*\mathbb{R}^3 \), and \( \Sigma \cap \Sigma^\sigma \) (\( \Sigma^\sigma \) denotes orthogonal complement with respect to the symplectic 2-form \( \sigma \)) is the Hamilton vector field for \( \sum_{j=1}^{3} F_j(y)\eta_j - A_j(y) \) where \( F_j(y) \) are the components of the vector intensity of the magnetic field \( B(y) \). In the present case \( \Sigma \cap \Sigma^\sigma = \mathbb{R}_{\parallel y_3}^{\perp 2} \). (Note that in the 2-D case, \( \Sigma \) is just a 2-D symplectic manifold). Many examples of integrable magnetic Hamiltonians are provided in [13].

As in the case of Schrödinger operator without a magnetic field, we may define complex branches of the energy surface by considering imaginary times. They glue along \( \Sigma \). For Hamiltonian (??) with a potential \( V \) sufficiently confining, the “magnetic classically allowed region” (MCAR) is a domain in \( \mathbb{R}^3 \) with 2 connected components in \( \pm y_3 > 0 \) bounded by the closed 2-D manifolds defined by \( \pi_y : T^*\mathbb{R}^3 \rightarrow \mathbb{R}^3 \) is the natural projection, and the “magnetic classically forbidden region” (MCFR) its complement.

For small \( \omega' \), the MCAR can be viewed as a deformation of the “classically allowed region” (CAR) for the Hamiltonian \( P_A^0(y, hD_y) = (hD_y)^2 + W(y) \) without a magnetic field.

We stress that in the MCFR we make the substitution \( v \rightarrow iv \) instead of \( \xi \rightarrow i\xi \) as in [10]. By this transformation the Hamiltonian remains real and gauge invariant. This is consistent with the following example of operator on \( L^2(\mathbb{R}^2) \)
\[ H(y, hD_y) = (hD_y^2)^2 + (hD_y - by_1)^2 + V_1(y_1) + \omega^2 y_3^2 \] (10)
which is unitarily equivalent (after partial Fourier transform with respect to \( x_2 \)) to the Schrödinger operator without a magnetic field \( H'(x, hD_x) = (hD_x)^2 + (hD_x - bx_1)^2 + V_1(x_1) \) (see [2, 6]). It turns out that our computations lead (up to the present accuracy) to the same quantities as [10], but without factor \( i \) at some places, see e.g. Proposition 1 below.

**Remark 2** Quantization of the kinetic term with a linear \( A(y) = (-y_1,0,0) \) (Landau gauge) was considered first in [24], p.496, leading to Landau levels with infinite degeneracy. In this case, the y-projection of classical trajectories consist in a family of helices, with arbitrary center. The generalized wave-functions are expressed in terms of a family of Hermite functions oscillating in the \( y_1 \)-direction around the center. This gives a hint at understanding the case of magnetic Schrödinger operator (MSO) \( P_A^M(y, hD_y) \) : degeneracy is lifted by the potential, that fixes somehow the center of the helix.

Notice that the potential well \( U_{E'(h)}(y) \) for \( \rho_0(y, \eta) = \eta^2 + W(y) \) at energy \( E'(h) = \frac{h^2}{4} (V(r_0) + \lambda_A(h)) \) with 2 connected components \( \pm E'(h) \) is given by
\[ U_{E'(h)}^\pm = \{ y : V(|y(y)|) - \frac{1}{\omega^2} (\kappa_1^2 + \kappa_2^2) \leq V(r_0) + \lambda_A(h), \pm y_3 > 0 \} \] (11)
Thus \( y_0^\pm \) (the “center” of each well) verifies \( y_0^\pm \in U^\pm_{E'} \), and \( \partial U^\pm_{E'(h)} \subset M^\pm \) if \( r \to V(r) \) grows fast enough at infinity and near 0, so that in particular \( W|_{y=0} > 0 \). Under these conditions, by the hyperplane symmetry, \( p_0^A \) has two potential wells \( U^\pm_{E'(h)} \) localized near \( y_0 = y_0^\pm \). Conditions on Floquet exponents (see Sect.3) ensure that \( W \) has nondegenerate minima at \( y_0^\pm \).

Taking Weyl quantization of \( p_A'(x, \xi) = (\eta - \omega' A(y))^2 + W(y) \), where \( A(y) = (-y_2, y_1, 0) \) (symmetric gauge) and \( \omega' = \frac{2\omega}{\sqrt{\langle \xi_2 \rangle}} \), we get the magnetic Schrödinger Hamiltonian

\[
P_A(y, hD_y)u(y; h) = (2\pi h)^{-3} \int_{\mathbb{R}^e} e^{i(y-z)\eta/h} p_A'(\frac{y+z}{2}, \eta)u(z) \, dz \, d\eta
\]

and by a change of variables

\[
P_A(y, hD_y)u(y; h) = (2\pi h)^{-3} \int_{\mathbb{R}^e} e^{i(y-z)(\eta + A(\frac{y+z}{2}))/h} p_0'_{y,h}(\frac{y+z}{2}, \xi)u(z) \, dz \, d\eta
\]

(13)

**Remark 3** For non linear magnetic potentials \( A(y) \) we need to modify this quantization, since it is no longer gauge invariant, see [15]. There are far-reaching generalisations of such h-PDO’s, in particular Berezin-Toeplitz operators, see [2], [3], [17].

5 WKB constructions for \( P_0^A \) and \( P_A^A \)

We will somehow relate the quasi-modes of \( P_0^A \) and \( P_A^A \) in \( M^\pm \), outside \( U^\pm_{E'(h)} \). Since we are looking for rather rough estimates on the eigenvalue splitting, it is sufficient here to search for WKB solutions of \( (P_0^A(y, hD_y) - \lambda_A(h))u(y; h) \sim 0 \) in the classically forbidden region (CFR) \( W(y) \geq E'(h) \), although \( P_0^A \) and \( P_A^A \) do not have the same ground state, e.g. the discussion in [7], Sect.7.2.

First we recall some known facts on tunneling for Schrödinger operators without a magnetic field. Let \( S^A_{E'(h)}(y) \) be Agmon distance from \( U^A_{E'(h)} \) to \( y \) for the Riemannian conformal metric \( (W(y) - E'(h))^{-1/2} \, dy^2 \), \( E'(h) = \frac{d^2}{dy^2}(V(y) + \lambda_A(h)) \) which vanishes on \( U_{E'} \). We know that the exponential decay of \( w \) from the well \( U_{E'} \), say, is given roughly by \( e^{-S^A_{E'}(y)/h} \), see [9], [17]. So we have to compute \( w \) near minimal geodesics \( \gamma_{E'(h)} \) between \( \partial U^\pm_{E'(h)} \). Such (finitely many) minimal geodesics are also called *librations* [2], [9], [11]. Within the required accuracy on tunneling rates, we could again replace \( E'(h) \) by \( E' \), which amounts to replace the librations by the instanton between \( U^\pm_{E'} = \{ y_0^\pm \} \).

Changing \( i \) to \( -i \) we may assume that in \( W(y) \geq E'(h) \) (CFR) \( P_A^A - E'(h) \) takes the form \( Q_0^A(y, hD_y) + E'(h) = (hD_y)^2 - W(y) + E'(h) \). Then the WKB solutions of \( (Q_0^A(y, hD_y) + E')w(y, h) = \lambda_A(h)w(y, h) \) are given by

\[
w(y; h) = e^{-\phi(y, E')/h} b(y, E'; h)
\]

(14)

In particular the phase function \( \phi \) solves (locally) Hamilton-Jacobi equation \( (\nabla \phi(y, E'))^2 - W(y) + E' = 0 \) and the amplitude \( b(y, E'; h) = b_0(y, E'; h) + h b_1(y, E'; h) + \cdots \) the transport equations. These WKB expansions can be justified by Agmon estimates near the minimal geodesics \( \gamma_{E'} \) as in [17]. Let now \( Q_A^A(y, hD_y) + E'(h) = (hD_y - \omega' A(y))^2 - W(y) + E'(h) \) be the corresponding Hamiltonian in MCFR. Recall that MCFR (with the magnetic field of strength \( \omega' \)) is a deformation \( \mathcal{O}(\omega') \) of the CFR (without the magnetic field).

To solve \( (Q_A^A(y, hD_y) + E'(h))u(y; h) \sim 0 \), we try

\[
u(y; h) = e^{-\phi(y, E')/h} b(y, E'; h)w(y, E'; h) = e^{-\phi(y, E') + \psi(y, E')/h} b(y, E'; h)c(y, E'; h)
\]

and replace \( E'(h) \) by \( E' \) as stated above. We find (omitting parameter \( E'(h) \), using (?) and (?)

\[
(Q_A^A(y, hD_y) + E')u(y; h) = (2\pi h)^{-3} \int \int \exp \left[ i \left( (y - z) (\eta + \omega' A(\frac{y+z}{2})) + \phi(z) + \psi(z)/h \right) \right]
\]

\[
\left( p_0'_{y,h}(\frac{y+z}{2}, \eta) + E' \right) b(z, E'; h)c(z, E'; h) \, dz \, d\eta
\]

(15)

(we have identified the operator with its Weyl symbol). Applying asymptotic stationary phase yields eikonal equation

\[
(-\omega' A(y) + \phi'(y) + \psi'(y))^2 - W(y) + E' = 0
\]

(17) which is Hamilton-Jacobi equation for Hamiltonian \( \langle \eta - \omega' A(y) + \phi'(y) \rangle^2 + W(y) + E' \). By a stability argument (?) has again a unique solution near \( \gamma_{E'} \), and can be solved perturbatively in \( \omega' > 0 \) small enough.

Namely, look for \( \psi(y) = \omega' \psi_0(y) + \omega'^2 \tilde{\psi}_1(y, \omega') \). Substituting into (?) we get at first order in \( \omega' \):

\[
2\nabla \phi(y) \nabla \psi_0(y) = 2(\nabla \phi(y), A(y)) \text{ which is a transport equation along the integral curves of Hamilton}
\]
vector field $H_{Q_0}$. Using Hamilton Eq. for $Q_0$, it can be written as $\frac{d}{dt}\psi_0(y(t)) = 2\left(-y_2\frac{\partial \omega}{\partial y_2} + y_1\frac{\partial \omega}{\partial y_1}\right)$ or in cylindrical coordinates $y_1 = r \cos \theta$, $y_2 = r \sin \theta$, $y_3 = y_3$, $\frac{d}{dt}\psi_0(x(t)) = 2\frac{\omega}{\partial y}(x(t))$ which can be integrated as (see also [10], Eq. (2.27)) $\psi_0(t) = \psi_0|_{\Omega} + 2\int_{\gamma} \frac{\omega}{\partial y}(x(s)) \, ds$. Higher order approximations in $\omega'$ are obtained similarly. In particular setting $\psi_1 = \psi_1 + \psi_2$, we find

$$2\nabla \phi(y)\nabla \psi_1(y) = -(\omega' y)^2 - \psi_0^2 + 2\langle A(y), \psi_0 \rangle = -|\psi_0|^2 - |A(y)|^2$$

or (see also Eq. (2.27) and Lemma 3.9 of [10]), $\frac{d}{dt}\psi_1(x(t)) = -\int |\psi_0'(x(s)) - A(x(s))|^2 \, ds$. The same type of arguments holds for transport equations defining $c(y, E', h)$.

Note that in dimension 1, the leading order term of the symbol $b(y, E'; h)c(y, E', h)$ would assume the familiar form $b(y, E'; h)c(y, E'; h) = \text{Const.} \exp\left[-\frac{1}{2} \int E'(x) \frac{d}{dx} \right]$, and we expect this formula to hold in the 3-D case as well.

Remark 4 The computation above is based on representation (7) in the real domain, can actually be carried over MCFR where the phase becomes complex (possibly purely imaginary), if we choose suitable branches of solutions with positive imaginary part. This can e.g. be achieved after performing a FBI transform of type (9) which allows for complex phases.

This eventually gives $u = u_{\text{WKB}}$ outside some $\omega'$-neighborhood of $\text{CAR} \{ y : W(y) \leq E'(h) \}$ of the form $\Omega^+_\omega \cup \tilde{\Omega}^-_{\omega'}$.

In fact CFR and MCFR may differ by $\mathcal{O}(\omega')$. To ensure that our WKB solutions overlap with the microlocal solutions obtained in Sect.3, we need to assume that representation (7) of the actual eigenfunction holds in a sufficiently large neighborhood (of size $\mathcal{O}(\omega')$) of the CAR $\{ y : W(y) \leq E' \}$ (without the magnetic field). This requires that we have a good control, sufficiently far away the microlocal wells, of the p.s.h. weights $-\phi_A$ constructed in Sect.3. It should be instructive to consider the model (8) from this viewpoint.

Let us summarize our constructions in the following:

Proposition 1: Assume $\tilde{\Omega}^+_\omega \cup \tilde{\Omega}^-_{\omega'} \subset \Omega^+_\omega \cup \Omega^-_{\omega'}$ where $\Omega^+_\omega$ have been defined at the end of Sect.2. Then there are WKB solutions $u_{\text{WKB}}$ as in (8) of $(P_{A}(x, hD_{x}) - E - \lambda_A(h))u_{\text{WKB}} \sim 0$ extending the quasi-modes $u^\pm$ of $P_{A}^{M^+}$ constructed in (9) along the (finite set) of minimal geodesics $\gamma_{E'}$ between $\partial U^+_{E'}(h)$.

As in the case of Schrödinger operator without a magnetic field, we can control the decay of eigenfunctions outside $U^+_{E'}$ by Agmon estimates. We start with a rough weighted energy estimate. Let $\mathcal{E}_a = \{ y : d_{E'}(U^+_{E'}, y) + d_{E'}(U^-_{E'}, y) \leq S_{E'} + a \} \subset M^+ \cup M^-$ for suitable $a > 0$, and $\tilde{\Omega} \subset \mathbb{R}^3$ large enough with $C^2$ boundary, such that $U^+_{E'} \subset \tilde{\Omega}$, $U^-_{E'} \cap \tilde{\Omega} = \emptyset$, $H = \partial \tilde{\Omega} \cap \mathcal{E}_a \subset M^+ \cap M^-$, see [9] p.43. Let also $\Phi$ be a Lipschitz function on $\partial \tilde{\Omega}$. Then for all $u \in C^2(\tilde{\Omega}, \mathbb{C})$, $u|_{\partial \tilde{\Omega}} = 0$, we recall from [9], Prop.7.2.25

$$\int_{\tilde{\Omega}} |(hD_x - A(x))(e^{\Phi/h} u)|^2 \, dx + \int_{\tilde{\Omega}} (W(x) - E' - |\Phi(x)|^2) e^{2\Phi/h} |u|^2 \, dx = \text{Re} \int_{\tilde{\Omega}} e^{2\Phi/h} (P_{A} - E') u(x) \bar{\nabla}(x) \, dx$$

The weight $\Phi$ should of course be related with $\phi + \psi$, but the term $(W - E' - |\Phi(x)|^2)$ in the second integral refers rather to the eikonal equation verified by $\phi$ alone, so instead of the decay observed in the WKB solution, we end up with this we would get in case $A(x) = 0$. So sharper estimates would require either to assume analyticity of the potential as in [10], or to change formula (7), to a formula verified by the ratio $\phi_A = u_{A}/u_0$ of ground states with and without a magnetic field. Note that in case $\lambda_A(h) = \lambda_0(h)$, which is achieved in particular (Bohm-Aharonov vector potential) when $\text{rot} \, A = 0$ in $\tilde{\Omega}$, necessarily non simply connected, and $\int A(x) \, dx \in 2\pi i \mathbb{Z}$ for all closed path $\gamma \subset \tilde{\Omega}$, then $(hD_x - A(x))\phi_A = 0$. This is due to an identity by R.Lavine and M.O’Carroll, see [2] p.93 and references therein, and leads in particular that $\phi_A$ is just a (x-dependent) phase factor. So in this case there would be no additional decay due to the magnetic field.

6 The Gap Formula and Estimate of the Splitting

As in the case of Schrödinger operator without a magnetic field, we relate the splitting to an integral of $\frac{\delta u}{\delta y_3}$ over $\Gamma \subset \{ y_3 = 0 \}$ that bisects the classically forbidden region near the minimal geodesics.
The gap formula is given by the interaction matrix

\[ w_{+-} = \hbar^2 \int_{\Gamma} (\omega(y) + \partial u_{-} / \partial y_3) dS(y) + \]

\[ \hbar \int_{\Gamma} (\omega(y) \langle A(y), \partial / \partial y_3 \rangle u_{-}(y) - u_{-}(y) \langle A(y), \partial / \partial y_3 \rangle u_{+}(y) ) dS(y) \]

(19)

The second term vanishes since \( A_3(y) = 0 \), hence (??) is identical to the gap formula without a magnetic field. This altogether with (??) yields an estimate for the splitting of the form

\[ e^{-\left( s_{\omega'} - o(\omega') \right) / \hbar} \leq E_1(h) - E_0(h) \leq e^{-\left( s_{\omega'} - o(\omega') \right) / \hbar} \]

(20)

but getting a sharper exponent requires to modify (??) as suggested above. Precise Agmon estimates also depend on the number of these geodesics, and on the structure of the eigenfunction \( u_A \) of \( P_A(y, hD_y) \) near \( \partial U_E^{\pm}(h) \), obtained in Sect.3.

ACKNOWLEDGEMENTS

We thank B. Helffer for interesting discussions on Agmon estimates in the presence of a magnetic field, and a referee for some useful references.
