Transcriptional effects of $^{177}$Lu-octreotate therapy using a priming treatment schedule on GOT1 tumor in nude mice

Johan Spetz$^1$, Britta Langen$^{1,2}$, Nils-Petter Rudqvist$^1$, Toshima Z. Parris$^3$, Emman Shubbar$^1$, Johanna Dalmo$^{1,4}$, Bo Wängberg$^3$, Ola Nilsson$^6$, Khalil Helou$^3$ and Eva Forssell-Aronsson$^{1,4}$

Abstract

Background: $^{177}$Lu-octreotate is used for therapy of somatostatin receptor expressing neuroendocrine tumors with promising results, although complete tumor remission is rarely seen. Previous studies on nude mice bearing the human small intestine neuroendocrine tumor, GOT1, have shown that a priming injection of $^{177}$Lu-octreotate 24 h before the main injection of $^{177}$Lu-octreotate resulted in higher $^{177}$Lu concentration in tumor, resulting in increased absorbed dose, volume reduction, and time to regrowth. To our knowledge, the cellular effects of a priming treatment schedule have not yet been studied. The aim of this study was to identify transcriptional changes contributing to the enhanced therapeutic response of GOT1 tumors in nude mice to $^{177}$Lu-octreotate therapy with priming, compared with non-curative monotherapy.

Results: RNA microarray analysis was performed on tumor samples from GOT1-bearing BALB/c nude mice treated with a 5 MBq priming injection of $^{177}$Lu-octreotate followed by a second injection of 10 MBq of $^{177}$Lu-octreotate after 24 h and killed after 1, 3, 7, and 41 days after the last injection. Administered activity amounts were chosen to be non-curative, in order to facilitate the study of tumor regression and regrowth. Differentially regulated transcripts (RNA samples from treated vs. untreated animals) were identified (change $\geq 1.5$-fold; adjusted $p$ value $< 0.01$) using Nexus Expression 3.0. Analysis of the biological effects of transcriptional regulation was performed using the Gene Ontology database and Ingenuity Pathway Analysis. Transcriptional analysis of the tumors revealed two stages of pathway regulation for the priming schedule (up to 1 week and around 1 month) which differed distinctly from cellular responses observed after monotherapy. Induction of cell cycle arrest and apoptotic pathways (intrinsic and extrinsic) was found at early time points after treatment start, while downregulation of pro-proliferative genes were found at a late time point.

Conclusions: The present study indicates increased cellular stress responses in the tumors treated with a priming treatment schedule compared with those seen after conventional $^{177}$Lu-octreotate monotherapy, resulting in a more profound initiation of cell cycle arrest followed by apoptosis, as well as effects on PI3K/AKT-signaling and unfolded protein response.

Keywords: GEPNET, NET, Radionuclide therapy, Radiation biology, Gene expression, Midgut carcinoid, PRRT, $^{177}$Lu-DOTATATE
Background

Neuroendocrine tumors (NETs) have frequently metastasized at the time of diagnosis. Following surgical tumor resection, adjuvant treatment with \(^{177}\)Lu-[DOTA\(^0\), Tyr\(^3\)]-octreotate (also written as \(^{177}\)Lu-octreotate or \(^{177}\)Lu-DOTATATE) is used for patients with somatostatin receptor (SSTR)-positive NETs, with complete remission in approximately 2% and partial remission in <30% of patients [1–3]. \(^{177}\)Lu is a medium-energy beta emitter (mean electron energy emitted per nuclear decay 147.9 keV) with a half-life of 6.6 days [4]. The mean range of the beta particles is 0.67 mm, allowing for a relatively contained dose distribution in tumors with high specific uptake of \(^{177}\)Lu-octreotate [5].

Several strategies have been proposed to further optimize the therapeutic effect of \(^{177}\)Lu-octreotate in NETs, including methods to increase tumor uptake and retention of \(^{177}\)Lu-octreotate [6]. We have previously demonstrated that tumor cells with neuroendocrine features increase their expression of SSTR after exposure to ionizing radiation in vitro [7, 8]. In vivo studies using the human small intestine NET model, GOT1 xenotransplanted to nude mice [9], have also shown an increased binding of \(^{111}\)In-DTPA-octreotide in tumor tissue after injection of \(^{177}\)Lu-octreotate [10, 11]. Furthermore, we have also shown a higher concentration of \(^{177}\)Lu in tumor tissue after administration of a low amount of \(^{177}\)Lu-octreotate (priming dose) given 24 h before the main administration of \(^{177}\)Lu-octreotate, compared with that found after single injection of the same total activity [12]. The priming treatment schedule thus resulted in higher mean absorbed dose to the tumor and increased anti-tumor effects. However, radiation-induced upregulation of SSTR has not been confirmed in vivo. Therefore, it is necessary to determine the mechanisms involved in the increased treatment efficacy observed when using a priming administration of \(^{177}\)Lu-octreotate before a second administration.

We have previously demonstrated the effects of exposure to radionuclides in animal models using expression microarray analysis. Initially, the effects of \(^{131}\)I or \(^{211}\)At exposure of normal tissues were demonstrated in mice and rats [13–18]. Then, studies on transcriptional effects of \(^{177}\)Lu-octreotate exposure of kidneys (to evaluate radiotoxicity) showed different responses in the kidney cortex and medulla [19]. Recently, expression microarray analysis of GOT1 tumors was presented, demonstrating radiation-induced apoptosis as an early response after a non-curative \(^{177}\)Lu-octreotate administration, followed by pro-survival transcriptional changes in the tumor during the regrowth phase [20, 21].

The aim of this study was to examine the transcriptional response in tumor tissue from animals treated with a priming administration of \(^{177}\)Lu-octreotate 24 h before a second \(^{177}\)Lu-octreotate administration to determine the molecular mechanisms responsible for the higher anti-tumor effect in comparison with \(^{177}\)Lu-octreotate monotherapy with the same total amount of \(^{177}\)Lu-octreotate.

Methods

Experimental design

This study was performed on 24 GOT1 tumor tissue samples obtained from previous experimental studies [12]. Briefly, GOT1 tumor tissue samples were transplanted subcutaneously in the neck of 4-week-old female BALB/c nude mice (Charles River, Japan and Germany) [9]. Tumor-bearing mice received a priming injection of \(^{177}\)Lu-octreotate (5 MBq) followed by a second injection of \(^{177}\)Lu-octreotate (10 MBq) 24 h later (hereafter referred to as 5 + 10 MBq). Control animals were injected with saline solution. During the study period, tumor volume was monitored using caliper measurement. Mean tumor volume relative to the time of the last injection was reduced in animals treated with \(^{177}\)Lu-octreotate (Fig. 1), with statistically significant differences compared with controls from day 7 until end of study (calculated using Student’s t test, \(p < 0.05\)). The minimum relative tumor volume in animals used in this study (mean = 0.39, SEM = 0.11) was measured 14 days after injection in animals killed after 41 days. The animals were killed at 1, 3, 7, or 41 days after the last injection, and tumor samples were frozen in liquid nitrogen and stored at −80 °C until analysis. Tumor-absorbed doses were determined for the 5 + 10 MBq administrations using the medical internal radiation dose (MIRD) formalism [22]. This resulted in a mean absorbed dose of 0.73, 2.3, 4.7, 6.4, and 6.4 Gy to the tumors calculated to 1, 3, 7, 41 days and at infinite time, respectively (Fig. 1). Drinking water and autoclaved food were provided ad libitum. Gene expression microarray analysis was performed on total RNA extracted from tumor samples from 15 animals treated with \(^{177}\)Lu-octreotate (Fig. 1), with statistically significant differences compared with controls from day 7 until end of study (calculated using Student’s t test, \(p < 0.05\)). The minimum relative tumor volume in animals used in this study (mean = 0.39, SEM = 0.11) was measured 14 days after injection in animals killed after 41 days. The animals were killed at 1, 3, 7, or 41 days after the last injection, and tumor samples were frozen in liquid nitrogen and stored at −80 °C until analysis. Tumor-absorbed doses were determined for the 5 + 10 MBq administrations using the medical internal radiation dose (MIRD) formalism [22]. This resulted in a mean absorbed dose of 0.73, 2.3, 4.7, 6.4, and 6.4 Gy to the tumors calculated to 1, 3, 7, 41 days and at infinite time, respectively (Fig. 1). Drinking water and autoclaved food were provided ad libitum. Gene expression microarray analysis was performed on total RNA extracted from tumor samples from 15 animals treated with \(^{177}\)Lu-octreotate (Fig. 1), with statistically significant differences compared with controls from day 7 until end of study (calculated using Student’s t test, \(p < 0.05\)). The minimum relative tumor volume in animals used in this study (mean = 0.39, SEM = 0.11) was measured 14 days after injection in animals killed after 41 days. The animals were killed at 1, 3, 7, or 41 days after the last injection, and tumor samples were frozen in liquid nitrogen and stored at −80 °C until analysis. Tumor-absorbed doses were determined for the 5 + 10 MBq administrations using the medical internal radiation dose (MIRD) formalism [22]. This resulted in a mean absorbed dose of 0.73, 2.3, 4.7, 6.4, and 6.4 Gy to the tumors calculated to 1, 3, 7, 41 days and at infinite time, respectively (Fig. 1).

Gene expression analysis

RNA extraction, hybridization, and data processing were performed for each of the 24 tumor samples individually as previously described [12]. In brief, total RNA was isolated using the RNeasy Lipid Tissue Mini Kit (Qiagen, Germany). Hybridization of RNA samples (RNA integrity numbers > 6.0) was performed at the Swegene Center for Integrative Biology (SCIBLU, Lund University, Sweden) on Illumina HumanHT-12 v4 Whole-Genome Expression BeadChips (Illumina, USA). Data processing was performed using the BioArray Software Environment (BASE)
Differentially regulated transcripts (treated versus control) were identified using an adjusted p-value cutoff of < 0.01 (Benjamini-Hochberg method) and |fold change| ≥ 1.5. The RNA samples from the control animals in this study have previously been used to analyze tumor RNA samples from animals treated with 15 MBq 177Lu-octreotate mono-injection, collected at 1, 3, 7, and 41 days after injection.

Microarray data were validated using quantitative reverse transcription-polymerase chain reaction (qRT-PCR) performed in triplicate with predesigned TaqMan® assays (Applied Biosystems, USA) specific for BAX, CDKN1A, FDFT1, GDF15, TGFBI, ACTA2, LY6H, LDLR, and EGR1 using a 7500 Fast Real-Time PCR System (Applied Biosystems). Differential expression was calculated using the ΔΔCt method, with EEF1A1, RPL6, and RPS12 used for normalization. cDNA was synthesized from the same RNA extracted for use in the microarray experiments, using SuperScript™ III First-Strand Synthesis SuperMix (Invitrogen, USA). cDNA reactions without addition of reverse transcriptase prior to qRT-PCR did not monitor any interfering genomic DNA.

Bioinformatics analysis
Heat maps and unsupervised hierarchical clustering of transcripts based on regulation patterns was performed in the R statistical computing environment (http://www.r-project.org, version 3.5.1), as previously described [20]. Functional annotation of differentially regulated transcripts was performed using the Gene Ontology (GO) database (http://www.geneontology.org) [11], with a p-value cutoff of < 0.05 (modified Fisher’s exact test). The annotated biological processes were stratified into eight categories as previously described [15]. Analysis of affected biological functions, canonical pathways, and upstream regulators was conducted using the Ingenuity Pathway Analysis (IPA) software (Ingenuity Systems, USA) with Fisher’s exact test (p < 0.05) as previously described [20, 21]. For direct comparison of the gene expression data obtained in this study with that of a more conventional treatment schedule (15 MBq single administration of 177Lu-octreotate, tumor samples collected at 1, 3, 7, and 41 days after injection), data from National Center for Biotechnology Information (NCBI) Gene Expression Omnibus (GEO), accession GSE80024 (previously described in [20]), was used.

Results
Time-dependent transcriptional response in GOT1 tumors after 177Lu-octreotate therapy with priming
A significant effect on gene expression levels was observed in GOT1 tumors after 177Lu-octreotate administration at all time points studied. In total, 187 differentially expressed genes were identified (microarray
data was validated using the qPCR assay (Additional file 1: Table S1 and Additional file 2: Figure S1)). The number of regulated transcripts varied with time after injection \((n = 31–82; \text{Fig. 2})\). Of the detected transcripts, 33 (66%), 41 (60%), 48 (59%), and 27 (87%) were uniquely regulated at 1, 3, 7 and 41 days, respectively. Thirty-eight regulated transcripts were shared between at least two of the four time points (Fig. 3). Hierarchical clustering of the transcriptional profiles revealed similarities and differences in gene expression over time (Fig. 2). Notably, several of the transcripts associated with Stress responses were significantly regulated at 3 and 7 days, while transcripts with a pivotal role in maintaining DNA integrity were only significantly regulated at 3 days after the last injection.

Comparing the functional annotation to GO terms with the results seen after 15 MBq \(^{177}\)Lu-octreotate monotherapy (from GEO accession GSE80024), 43% of significant annotations were shared overall between the two treatment regimens (Fig. 2). Categorization of these annotated biological processes revealed that a majority of transcripts associated with gene expression integrity (57%) and organismic regulation (52%) were found in both 5 + 10 MBq and 15 MBq experiments. For the remaining six categories, most annotations were unique for the 5 + 10 MBq setting (48, 46, 45, 36, 30 and 0% shared annotations for the categories Metabolism, Cell cycle & differentiation, Stress responses, Cellular integrity, Cell communication, and DNA integrity, respectively). Furthermore, most of the annotations shared between the different regimens occurred at 1 and 7 days (90 and 58% shared annotations, respectively) after the last injection of \(^{177}\)Lu-octreotate, while 3 and 41 days showed more unique annotations (29 and 19% shared annotations, respectively).

**Differential effects on tumor cell proliferation and apoptosis in GOT1 tumors after \(^{177}\)Lu-octreotate therapy with priming**

Analysis of affected biological functions using IPA predicted that a variety of functions related to tumor cell proliferation were significantly regulated at early time points after the last injection of \(^{177}\)Lu-octreotate (1 and 3 days), due to the regulation of, e.g., the CDKN1A \((p21)\), GDF15, and SGK genes (Table 1). Apoptotic

---

**Fig. 2** Distribution of significantly regulated genes after \(^{177}\)Lu-octreotate therapy with priming. Expression profiles of the 187 significantly regulated transcripts after i.v. injection of 5 + 10 MBq \(^{177}\)Lu-octreotate at 1, 3, 7, or 41 days after the last injection and annotation of enriched GO terms. Unsupervised hierarchical clustering was performed based on expression profiles. The mean absorbed dose to tumors processed for transcriptional analysis is indicated by the corresponding time point. Red and green indicate up- and downregulated transcripts (treated versus control, fold change \(\geq 1.5,\) FDR-adjusted \(p < 0.01\)), respectively. In the lower segment, orange and blue indicate significant annotation (modified Fisher’s exact test, \(p < 0.05\)) of a gene to a GO term in a specified category. Orange indicates the GO annotation was significant both in animals treated with 5 + 10 MBq and in animals treated with 15 MBq single administration of \(^{177}\)Lu-octreotate (from GEO accession GSE80024), while blue indicates a significant GO annotation only in animals receiving 5 + 10 MBq \(^{177}\)Lu-octreotate.
processes were activated at 3 days after the last injection ($z$ score = 2.0, $p = 2.2 \times 10^{-5}$), due to the regulation patterns of, e.g., the BAX, GADD45A, and TNFRS10B genes. Biological functions affected at 7 days were mainly related to cell migration, while a broader variety of functions (e.g., tumor sphere formation, proliferation of cancer cells, and budding of mitochondria) were affected during regrowth (41 days), due to the regulation of, e.g., SOX2, CXCR7, and LGALS1.

Pathway analysis using IPA revealed a variety of significantly affected canonical signaling pathways ($p < 0.05$, Table 2). Several of the detected pathways are known to be involved in cancer development (e.g., PI3K/AKT signaling at 1 day, p53 signaling at 3 and 7 days, and Wnt/β-catenin signaling at 41 days) [25]. p53 (regulator of, e.g., DNA damage response) was also identified as an activated upstream regulator at early time points after the last injection of $^{177}$Lu-octreotate ($z$ scores −2.0 and 2.6, $p$ values 8.1 $\times 10^{-10}$ and 2.0 $\times 10^{-5}$, respectively) and PARP1 (poly (ADP-ribose) polymerase 1, involved in DNA strand break repair) at 7 days ($z$ score −2.0, $p$ value 3.7 $\times 10^{-7}$) after the last injection of $^{177}$Lu-octreotate.

Figure 3: Expression profiles of commonly regulated transcripts after $^{177}$Lu-octreotate therapy with priming. Differential expression (treated vs. control) of the 38 significantly regulated transcripts shared between at least two of the studied time points, after i.v. injection of 5 + 10 MBq $^{177}$Lu-octreotate at 1, 3, 7, or 41 days after injection. Transcripts with fold change $\geq 1.5$ and FDR-adjusted $p < 0.01$ were considered significantly regulated; annotation of enriched Gene Ontology terms was performed using the Gene Ontology database (modified Fisher’s exact test, threshold $p < 0.05$). Up- and downregulation is indicated by positive and negative values, respectively.

**Discussion**

The use of priming followed by a second administration of $^{177}$Lu-octreotate is a promising method to increase the efficacy of $^{177}$Lu-octreotate therapy of SSTR-expressing tumors. In the present study, gene expression profiling was used to study the mechanisms involved in the anti-tumor effect observed after treatment with $^{177}$Lu-octreotate including priming [12].

The anti-tumor effects of $^{177}$Lu-octreotate with different priming and second administration protocols have been presented in detail by Dalmo et al. [12]. The group of animals used in the present investigation showed tumor volume regression followed by tumor regrowth, i.e., a suboptimal treatment, chosen in order to be able to study also the regrowth period. Tumor mean absorbed doses were estimated to 6.4 Gy at infinity time for the 5 + 10 MBq administrations. This should be compared with the absorbed dose of 4.0 Gy to tumors in mice treated with 15 MBq single administration. Furthermore, statistically significant differences were observed in the tumor activity concentration between mice treated with and without priming therapy [12].

$^{177}$Lu decays by beta emission but also has a gamma component [4]. The majority of the absorbed dose is delivered by the beta-particle, and although the gamma radiation has longer range, the photon contribution only marginally influences the absorbed dose due to the low yield of the emitted photons [5]. Even though this means the cross-absorbed fraction (dose delivered from, e.g., tumor to surrounding healthy tissues) is negligible,
adverse effects in healthy tissues are still an issue due to the uptake of $^{177}$Lu-octreotide in healthy organs. The main dose-limiting organ for $^{177}$Lu-octreotide treatment are the kidneys, which accumulate the radiopharmaceutical partly due to SSTR expression but also because of reabsorption in proximal tubular cells [26]. While outside the scope of this work, the effects of $^{177}$Lu-octreotide on the kidney function and gene expression are important considerations and have been studied extensively by both us and others [19, 27–32].

A comparison of differentially regulated transcripts revealed significant differences across time points and indicated that different cellular functions are affected depending on the time after administration of $^{177}$Lu-octreotide. Approximately 60% of the transcripts differentially regulated at 1, 3, and 7 days were uniquely regulated at each time point, and at 41 days, the value was even higher with 87%. The microarray analysis revealed two response stages along the investigated time course, with a similarity between tumor responses at early time points (up to 7 days) compared with the response during tumor regrowth (41 days). This pattern is also illustrated by the 38 regulated transcripts shared between at least two of the time points studied, of which only four were found in the 41 days group. It is interesting to notice that the direction of regulation changed between early and late time points for $^{177}$Lu-octreotide.

### Table 1 Predicted biological functions affected in G0T1 tumors after $^{177}$Lu-octreotate therapy with priming

| Affected function                        | $z$  | $p$  | Targets from transcriptional data |
|-----------------------------------------|------|------|-----------------------------------|
| 1 day                                   |      |      |                                   |
| Hyperpolarization                       | –    | $1.7 \times 10^{-4}$ | ↑SGK, ↓SCN9A |
| G2 phase arrest in cancer               | –    | $3.3 \times 10^{-4}$ | ↑SGK, ↑CDKN1A |

| Budding of mitochondria                 | –    | $1.3 \times 10^{-3}$ | ↓LGALS1 |

Significantly affected biological functions identified with IPA (Fisher’s exact test, $p < 0.05$), ranked according to the lowest $p$ value, for each time point. $z$ scores indicate activation state of biological function; $z > 2$ indicates activation, and $z < 2$ indicates inhibition. Up and down arrows indicate upregulated and downregulated genes in tumor samples from treated animals compared with controls, respectively. $\downarrow$ indicates the function was not affected in animals treated with 15 MBq single administration of $^{177}$Lu-octreotate (from GEO accession GSE80024).
Table 2 Predicted canonical pathways affected in GOT1 tumors after $^{177}$Lu-octreotate therapy with priming

| Ingenuity Canonical Pathways                                      | p       | Targets from transcriptional data               |

Significantly affected canonical pathways identified with IPA (Fisher’s exact test, p < 0.05), ranked according to the lowest p value, for each time point. Up and down arrows indicate upregulated and downregulated genes in tumor samples from treated animals compared with controls, respectively. $\uparrow$ indicates the pathway was not affected in animals treated with 15 MBq single administration of $^{177}$Lu-octreotate (from GEO accession GSE80024).

lines, e.g., KRJ-I, but not in others, e.g., BON [34, 35]. The regulation of TGFβ1 in the present study is in coherence with results seen after 15 MBq $^{177}$Lu-octreotate monotherapy of GOT1 tumors [20] and may suggest functioning TGFβ-signaling in GOT1 tumors, but this finding remains to be proven.

IPA analysis of the data from 1 day after the last injection predicts that the initial response to treatment is growth arrest, based on, e.g., upregulation of the CDKN1A and SGK genes. Effects on tumor cell proliferation were also seen at 3 days after the last injection, along with an activation of apoptosis. This is in accordance with results seen after injection of 15 MBq $^{177}$Lu-octreotate [20]. However, in the present study on priming schedule, the target genes for the prediction of apoptosis activation suggest that both the intrinsic (via, e.g., the BAX, GADD45A, and PBK genes [36–38]) and extrinsic (via, e.g., the TNFRSF10B and NGFRAP1 genes [33, 39]) apoptotic pathways are involved in the response. This is in contrast to the observed effects of 15 MBq monotherapy where only the intrinsic apoptotic pathway was affected [20]. In comparison with the results from the 15 MBq monotherapy study, no anti-apoptotic functions were affected during regrowth in the present study, and the downregulation of, e.g., CXCR7 and LGALS1 suggests an inhibition of cell proliferation. This may account for the slower regrowth observed with the priming treatment schedule.

In order to identify alterations in key regulatory pathways after $^{177}$Lu-octreotate therapy, analysis of IPA canonical pathways and upstream regulators was performed. Both the pathway and upstream regulator analysis revealed an effect on p53-signaling at 3 and 7 days after injection, with a predicted activation at 3 days (z score 3.3). Previous studies have shown that radiation exposure resulted in the activation of the p53 signaling pathway which, depending on the extent of DNA damage, promotes cell survival (by cell cycle arrest and DNA damage repair), or intrinsically activates cell death mechanisms such as apoptosis [40–
downregulated genes in tumor samples from treated animals compared with controls, respectively.

Table 3 Predicted upstream regulators affected in GOT1 tumors after \(^{177}\)Lu-octreotate therapy with priming

| Upstream regulator | \(z\) | \(p\) | Targets from transcriptional data |
|-------------------|------|------|----------------------------------|
| **1 day**         |      |      |                                  |

| mir-140           | –    | 1.3 \(\times 10^{-3}\) | ↓SOX2 |

Significantly affected upstream regulators identified with IPA (Fisher’s exact test, \(p < 0.05\)). ranked according to the lowest \(p\) value, for each time point. \(z\) scores indicate activation state of the upstream regulator; \(z > 2\) indicates activation, and \(z < -2\) indicates inhibition. Up and down arrows indicate upregulated and downregulated genes in tumor samples from treated animals compared with controls, respectively. ↑ indicates the upstream regulator was not affected in animals treated with 15 MBq single administration of \(^{177}\)Lu-octreotate (from GEO accession GSE80024).

The predicted inhibition and activation of upstream regulators ANXA2 and KDMSB, respectively, to target genes such as BAX, CDKN1A, GADD45A, and PBK further suggests that tumor growth is suppressed via p53-mediated processes [43]. An effect on p53-signaling was also seen in GOT1 tumors in response to 15 MBq \(^{177}\)Lu-octreotate monotherapy, albeit only at 3 days after injection (compared with 3 and 7 days following treatment with priming) [20]. However, in the present study, PI3K/AKT signaling was also affected at 1 day, suggesting an increased effect on cell cycle arrest via upregulation of PPP2R2B, CDKN1A, and GDF15. The effect on the extrinsic apoptotic pathway (death receptor signaling) was also observed in the pathway analysis at 3 days, owing to the regulation of the ACTA2 and TNSRF10B genes. Unfolded protein response (UPR) was also affected at 3 days. UPR is a stress response pathway which is caused by endoplasmic reticulum stress. Protein folding occurring in the endoplasmic reticulum is extremely sensitive to environmental changes regarding, e.g., reactive oxygen species (which could be caused by, e.g., \(^{177}\)Lu-octreotate-induced radiolysis of water or downstream effects of irradiation-induced cellular damage), hypoxia, or inflammatory stimuli, and studies have shown that endoplasmic stress can induce apoptosis (mediated by, e.g., JNK signaling) and enhances the radiosensitivity of tumor cells by degradation of RAD51 and subsequent reduction of double-strand break repair [44, 45]. Furthermore, the prediction of PARP1 as an inhibited upstream regulator at 7 days also suggests an impaired ability to repair DNA double-strand breaks. These responses were not seen in the study of 15 MBq \(^{177}\)Lu-octreotate monotherapy and may be contributing factors in the increased anti-tumor effect of a priming treatment.
schedule. Interestingly, we have previously demonstrated that the NAMPT inhibitor GMX1778 enhances the effects of single injection of 7.5 MBq $^{177}$Lu-octreotate treatment and induces a prolonged antitumor response in the same animal model as in the present study [46], an effect that may be related to PARP1 activation status.

Generation of GOT1 xenografts in nude mice is performed by first establishing a tumor into a few mice, by subcutaneous injection of cells from in vitro culture. After 4–6 months, the mice develop tumors at the site of injection. Tumors are then allowed to grow for several months and are then divided into 1-mm tissue pieces and transplanted into a larger number of mice, usually ca 60–100 each time. The tumor take is relatively low, tumors appear at different time points, the tumors grow slowly, and the growth rate differs much between animals within a transplantation batch, which results in a large variation in tumor sizes at a certain time point. Unfortunately, this sometimes results in a low number of tumor-bearing animals being available for experiments at a certain time, which limits the number of animals per treatment group. However, to our knowledge, the GOT1 model is unique in having a traceable neuroendocrine origin (a liver metastasis from a well-differentiated, serotonin-producing (enterochromaffin cell type) ileal NET) as well as harboring no mutations in p53 (mutated/dysfunctional p53 is usually not observed in patients) [47]. We therefore consider GOT1 to be the most representative model for studying small intestine NETs outside of using patient samples. Furthermore, the multifaceted differences in gene expression seen between treated and untreated groups in this work despite the strict statistical thresholding (fold change > 1.5, FDR-adjusted $p < 0.01$) suggests that gene regulation can be seen also with these group sizes.

**Conclusions**

Microarray analysis characterized two stages of pathway regulation for the priming schedule (up to 1 week and around 1 month) which differed distinctly from cellular responses observed after monotherapy.

The priming treatment schedule resulted in induction of p53-mediated cell cycle arrest and apoptosis as well as extrinsically-mediated apoptosis in GOT1 tumors. Together with effects on PI3K/AKT-signaling and unfolded protein response, these findings suggest increased cellular stress in the tumors after a priming treatment schedule compared with conventional $^{177}$Lu-octreotate monotherapy. Furthermore, downregulation of, e.g., CXCR7 and LGALS1 suggests an inhibition of cell proliferation at late time points after the last injection, which may explain the slow regrowth compared with tumors in animals treated with monotherapy.

This study was supported by grants from the Swedish Research Council, the Swedish Cancer Society, BioCARE - a National Strategic Research Program at University of Gothenburg, the Swedish state under the agreement between the Swedish government and the county councils – the ALF-agreement (ALFGBG-725031), the King Gustav V Jubilee Clinic Cancer Research Foundation, the Johan Jansson Foundation, the Lars Hierta Memorial Foundation, the Wilhelm and Martina Lundgren Research Foundation, the Assar Gabrielsson Cancer Research Foundation, the Adlerbertska Research Foundation, the Royal Society of Arts and Sciences in Gothenburg (KVVS) and Sahlgrenska University Hospital Research Funds.

**Availability of data and materials**

The datasets generated during and/or analyzed during the current study are available in NCBI Gene Expression Omnibus, GEO accessions GSE80022 ([https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE80022](https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE80022)) and GSE80024 ([https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE80024](https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE80024)).

**Authors’ contributions**

JS, JD, and EFA conceived and designed the experiments. JS and JD performed the animal experiments. JS, BL, NPR, TZP, and ES performed tissue sample processing. JS, BL, and NPR performed bioinformatic analyses and data visualization. JS, BL, NPR, TZP, ES, BW, ON, KH, and EFA analyzed and interpreted the data. JS, BW, ON, KH, and EFA contributed reagents/materials/analysis tools. JS and EFA drafted the manuscript. All authors contributed to the review and editing of the manuscript and approved the final manuscript.

**Ethics approval and consent to participate**

This study was carried out in strict accordance with the recommendations in the directive 2010/63/EU regarding the protection of animals used for scientific purposes. The study protocol was approved by the Ethical Committee for animal research at University of Gothenburg, Gothenburg, Sweden (this study was authorized specifically under file no. 118-11).
