(May 10, 2018)

Phase transitions involving vortex lattices in the high temperature superconductors are an area of active study [12,13]. Below a critical value of the magnetic field, vortex lattices in YBa$_2$Cu$_3$O$_{7-\delta}$ (YBCO) [3,4] and Bi$_2$Sr$_2$CaCu$_2$O$_8$ (BSCCO) [5,6] undergo a first order phase transition. This conclusion comes from latent heat measurements [6] as well as jumps in the resistivity [3,8,9]. We point out an alternative possibility that the melting transition actually occurs in a system using resistivity measurements, only the defect lines act as defects and in the magnetization [3,9]. It has generally been assumed that this is a melting transition from a vortex solid to a vortex liquid. In this paper we suggest the possibility that the melting transition actually occurs in two steps as the temperature increases; the first step is a first order premelting transition from an ordinary vortex lattice to a soft solid with a small but finite shear modulus, and the second step is the first order melting of the soft solid into a vortex liquid. In this paper we focus on the first step. We present an analytic theory of a first order premelting transition in which the shear modulus jumps discontinuously. The transition is induced by interstitial and vacancy line defects in the vortex lattice which soften the shear modulus $\epsilon_{66}$. We find good agreement with the experimental curve of transition temperature versus field, latent heat, and magnetization jumps for YBCO and BSCCO. In the soft solid phase the superconducting phase coherence along the field is destroyed by the wandering of the defect lines which become entangled in the vortices of the soft solid lattice [10,11].

Let us describe our scenario for premelting. Our approach follows that of Granato who showed that interstitial atoms soften the shear modulus of ordinary crystals and lead to a first order transition [11,12]. We start with a vortex lattice in a clean layered superconductor with a magnetic field $H$ applied perpendicular to the layers along the c-axis. We consider the vortices to be correlated stacks of pancake vortices. We will assume that the transition is induced by topological defect lines, i.e., vacancies and interstitials. In a Delaunay triangulation [12] a vacancy or an interstitial in a triangular lattice is topologically equivalent to a pair of bound dislocations [13] as well as to a twisted bond defect [14]. High temperature decoration experiments [15] and Monte Carlo simulations [14] have found such defects to be thermally excited. The introduction of these defects softens the elastic moduli. Since the energy to introduce interstitials and vacancies is proportional to the elastic moduli, softening makes it easier to introduce more defects. The softening also increases the vibrational entropy of the vortex lattice which leads to a premelting transition. The transition is driven by the increased vibrational entropy of the vortex lines of the lattice, and not by the entropy of the wandering of the defect lines. In fact Frey, Nelson and Fisher [10] showed that a phase transition driven by the entropy of wandering flux lines occurs at a much higher magnetic field than what is observed experimentally. In the vicinity of the experimentally observed first order phase transition, wandering in the transverse direction by more than a lattice spacing is energetically quite costly and therefore rare. (The energy scale is set by $\epsilon_o s$ [13]. Here $s$ is the interplane spacing and $\epsilon_o$, the energy per unit length of a vortex, is given by $\epsilon_o = (\phi_o/4\pi\lambda_{ab})^2$ where $\phi_o$ is the flux quantum and $\lambda_{ab}$ is the penetration depth for currents in the ab plane.)

Experimentally the resistivity jumps up at the transition from zero to a finite value as the temperature increases. This is consistent with our model since the soft solid will have a finite resistivity due to the motion of interstitial (and vacancy) lines. The barrier for the motion of interstitials is very small [13] and is of order $10^{-3}E_o$ per unit length, where $E_o = 2\epsilon_o$. The defect lines act like a liquid of lines existing in a soft solid host. Notice that if one tries to measure the shear modulus of such a system using resistivity measurements, only the defect lines would move relative to the pinned soft solid and one would deduce the shear modulus was zero [12,14].

The first order transition is nucleated in a small re-
Fourier transform $u^q_n$, $f$ and the vibrational partition function $Z_n$ denote the displacement of the th plane from its equilibrium position by $o = \pi \xi^2_b$ of the normal core of a pancake [23]. $u_B$ and $u_T$ are the real and imaginary parts of $u(k, q)$ and $\iota f(x, y)$. The elastic free energy functional associated with these distortions is

$$F_{el} = \frac{1}{2} \sum_{kq} \sum_{ij} u_i(q, k) a_{ij} u^*_j(q, k)$$

where we have divided by the area $\pi \xi^2_b$ of the normal core of a pancake [23]. $u_B$ and $u_T$ are the real and imaginary parts of $u(k, q)$ and $\iota f(x, y)$. The elastic free energy functional associated with these distortions is

$$F_{el} = \frac{1}{2} \sum_{kq} \sum_{ij} u_i(q, k) a_{ij} u^*_j(q, k)$$

where $i$ and $j \in \{x, y\}$, the volume per pancake vortex is $v_o = s \phi_0 / B$, and $s$ is the interplane spacing. The $k$ sum is over a circular Brillouin zone $K^2 = 4\pi B^2 / \phi_0$. The matrix $a_{ij}$ is given by $a_{ij} = c_B k_i k_j + (c_6 k^2 + c_44 Q^2) \delta_{ij}$ where $c_B$, $c_6$, and $c_44$ are the bulk, shear, and tilt moduli, respectively. $c_B = c_{11} - c_{66}$ for a hexagonal lattice. $Q^2 = 2(1 - \cos q s) / s$. Diagonalizing $a_{ij}$ leads to 2 eigenvalues: $A(kq) = c_{11} k^2 + c_{44} Q^2$ and $A_T = c_{66} k^2 + c_{44} Q^2$, where $A$ is the diagonal matrix, the subscript $T$ denotes longitudinal and $T$ denotes transverse. Using this, we can integrate over $u$ in (3) and the remaining sums over $k$ and $q$ are done numerically. At low fields ($b = B / H_c2 < 0.25$), the elastic moduli are given by [1, 2]

$$c_{66} = \frac{B \phi_0 \zeta}{(8 \pi \lambda c)^2}$$

$$c_{11} = \frac{B^2 [1 + \lambda^2 (k^2 + Q^2)]}{4 \pi [1 + \lambda^2 Q^2] [1 + \lambda^2 (k^2 + \lambda^2 Q^2)]}$$

$$c_{44} = \frac{B^2}{4 \pi [1 + \lambda^2 Q^2] [1 + \lambda^2 (k^2 + \lambda^2 Q^2)] + \frac{B \phi_0}{32 \pi^2 \lambda^2}} \times \ln \frac{\xi^2_{ab}}{K^2_o + (Q/\gamma)^2 + \lambda^2} + \frac{B \phi_0}{32 \pi^2 \lambda^4 Q^2} \ln(1 + \frac{Q^2}{K^2_o})$$

where $\lambda_c$ is the penetration depth for currents along the c-axis, $\gamma = \lambda_c / \lambda_b$, and $\zeta = 1$. At high fields ($b > 0.5$) [11, 23], $c_{66}$ is altered by the factor $\zeta \approx (1 - 0.5 \kappa^{-2} - (1 - b)^2 (1 - 2 \delta_b) - 0.29 \delta_b^2$ and the penetration depths in $c_{11}$ and $c_{44}$ are replaced by $\lambda^2 = \lambda_c^2 / (1 - b)$ where $\lambda$ denotes either $\lambda_a$ or $\lambda_c$. In addition, the last two terms of $c_{44}$ are replaced by $B \phi_0 / (16 \pi^2 \lambda^2)$. These replacements guarantee that the elastic moduli vanish at $H_c2$. For YBCO the temperature dependence of the penetration depths and coherence lengths are given by $\lambda(T) = \lambda(0) (1 - (T / T_c))^{-1/3}$ [23] and $\lambda_b(T) = \xi_b(0) (1 - (T / T_c))^{-1/2}$, respectively. For BSCCO whose premelting field is two orders of magnitude below $H_c2$, $\lambda^2(T) = \lambda^2(0) (1 - (T / T_c))^{1/4}$ and $\xi^2_{ab}(T) = \xi^2_{ab}(0) (1 - (T / T_c))^{1/2}$ [23].

The free energy density $f_w$ due to the energy cost of adding a vacancy or interstitial vortex line is difficult to calculate accurately [14]. However, we can write down a plausible form for $f_w$ by noting that a straight line defect parallel to the c-axis produces both shear and bulk (but not tilt) distortions of the vortex lattice. For example, if a defect at the origin produces a displacement...
that satisfies $\nabla \cdot \mathbf{u} = \nu \delta(\mathbf{r})/s$ where $\delta(\mathbf{r})$ is a two dimensional delta function, then $u_0(k) = ik_\alpha/k^2$. Inserting this in (4), we find that $f_w = \left(\alpha_6 + \mathbf{\tau}_B\right)/2$ where

$$\mathbf{\tau}_B = \sum_k c_B(q = 0, k).$$

Generalizing this to allow for a more complicated distortion and for a concentration $n$ of line defects, we write

$$f_w = \int_0^n dn(\alpha_1 c_{66} + \alpha_2 \mathbf{\tau}_B)$$

where $\alpha_1$ and $\alpha_2$ are dimensionless constants. We expect the isotropic distortion to be small, i.e., $\alpha_2 \ll 1$, and the shear deformation to dominate, i.e., $\alpha_1 \gg \alpha_2$. Integrating over $n$ allows the elastic moduli to depend on defect concentration. We will assume that $\mathbf{\tau}_B$ is independent of $n$ since we believe that the bulk modulus of the vortex solid is roughly the same as that of the soft solid phase. To find $c_{66}(n)$, we use its definition

$$c_{66} = \partial^2 f/\partial \varepsilon^2$$

where $\varepsilon$ is the shear strain. Assuming that $\mathbf{\tau}_B$ has negligible shear strain dependence, we find

$$c_{66}(n) = c_{66}(0) + \alpha_1 \int_0^n \left(\partial^2 c_{66}(n)/\partial \varepsilon^2\right)dn$$

where $c_{66}(n)$ enters our expression (6) for $f_w$ yields

$$f_w = \frac{c_{66}(n = 0)}{\beta} (1 - e^{-\alpha_1 \beta n}) + \alpha_2 \mathbf{\tau}_B n$$

The last term we need to consider is $f_{\text{wan}}$, the free energy due to the wandering of the defect lines over distances large compared to the lattice spacing. We can estimate $f_{\text{wan}}$ with the following expression

$$f_{\text{wan}} \approx -\frac{k_B T}{\ell_z a_o^2} \ln(m_t)$$

where $m_t = 3$ for a triangular lattice (BSCCO) and $m_t = 4$ for a square lattice (YBCO). $\ell_z$ can be thought of as the distance along the $z$-axis that it takes for the defect line to wander a transverse distance of one lattice spacing $a_o$. To go from one vacancy or interstitial site to the next, the defect line segment must jump over the barrier between the two positions. This gives $\ell_z$ a thermally activated form: $\ell_z \sim \ell_o \exp(-E/k_B T)$, where $E = a_o (\varepsilon_1/\varepsilon_B)^{1/2}$ and $\varepsilon_1$ is the line tension and is given by $\varepsilon_1 \sim (\varepsilon_o/\gamma)^2 \ln(a_o/\ell_o)$. Numerical simulations indicate that the barrier height $\varepsilon_B$ is small and we use $\varepsilon_B = 2.5 \cdot 10^{-3} \varepsilon_o$. $f_{\text{wan}}$ itself is quite small compared to the other terms because of the high energy cost of vortex displacements. For example, in the soft solid phase at the transition $f_{\text{wan}}$ is about two orders of magnitude smaller than $f_w$ or $f_{\text{vib}}$. Thus the transition is not driven by a proliferation of wandering defect lines because near the transition the high energy cost of vortex displacements is not sufficiently offset by the entropy of the meandering line.

Before we plot $f$ versus $n$, we note that the difference between $B$ and $H$ is negligible for YBCO but can be a significant fraction of the premelting field $H_p$ for BSCCO. To find the value of $B$ to use in the Helmoltz free energy density $f$, we minimize the Gibbs free energy density $G$, i.e., $\partial G/\partial B = 0$ where $G = f - B \cdot H \cdot \mathbf{H}/4\pi$. Since the concentration dependence of $B$ is negligible, we find $B$ for $n = 0$ for each value of $H$ and $T$. Typical plots of $\Delta f = f(n) - f(0) = f_w + \Delta f_{\text{vib}}$ versus $n$ are shown in the inset of figure 1. The double well structure of $\Delta f$ is characteristic of a first order phase transition. The equilibrium transition occurs when both minima have the same value of $\Delta f$. We associate the minimum at $n = 0$ with the vortex solid and the minimum at finite $n$ with a soft vortex solid that has a small but finite shear modulus. The defect concentration at the transition is only a few percent. At higher concentrations $\Delta f$ increases with increasing $n$ because introducing defects costs compression energy which is proportional to the bulk modulus. Thus defects do not proliferate. As an estimate of the softness at the transition, for $n = 5\%$, $c_{66}(n) \sim 0.2 c_{66}(0)$ for BSCCO. The strain field $\varepsilon_{oij}(k)$ produced by the defect determines whether the shear modulus is zero in the high temperature phase. For dislocation loops, $\varepsilon_{oij}(k)$ is singular as $k \to 0$, and the shear modulus is zero at $k = 0$. For vacancy and interstitial lines $\varepsilon_{oij}(k)$ is finite, and hence the shear modulus is nonzero.

In figure 1 we fit the experimental first order transition curves in the $H - T$ plane using 2 adjustable parameters: $\alpha_1$ and $\alpha_2$. As expected, $\alpha_1 \gg \alpha_2$ and $\alpha_2 \ll 1$ (see Figure 1). The geometrical quantity $\beta$ can have several values for a given lattice structure, depending on which planes are sheared. We choose $\beta = \pi \tan\phi$ where $\phi$ is the angle between primitive vectors. Decoration experiments on BSCCO find a triangular lattice, so use $\phi = 60^\circ$. For YBCO we choose $\phi = 44.1^\circ$ which is very close to a square lattice which has $\phi = 45^\circ$. Maki has argued that the $\delta$-wave symmetry of the order parameter yields a square vortex lattice tilted by $45^\circ$ from the $a$-axis. Experiments on YBCO find $\phi$ ranging from $36^\circ$ to $45^\circ$.

We can calculate the jump in magnetization $\Delta M$ at the transition using $\Delta M = -\partial \Delta G/\partial H|_{T = T_p}$. The jump...
in entropy $\Delta s$ is given by $\Delta s = -v_o \partial \Delta G / \partial T|_{H=H_p}$ where $\Delta s$ is the entropy change per vortex per layer. The results are shown in Figure 2. We have checked that our results satisfy the Clausius-Clapeyron equation $\Delta s = -(v_o \Delta B/4\pi) dH_p / dT$. We obtain good agreement with experiment well below $T_c$. Near $T_c$ it is thought that the entropy jump is enhanced by microscopic degrees of freedom [23,24] which are not included in our model.

We can compare our results with the Lindemann criterion by calculating the mean square displacement $< |u|^2 >$ at the transition using eq. (9): $< |u|^2 > = -(2k_B T/v_o) \sum_{akq} q^2 \ln Z_{\alpha \beta} / \partial (\alpha q) \partial A(\alpha q)$ where $A$ is the diagonal matrix similar to $a_{ij}$ and $\alpha$ labels the 2 eigenvalues. Defining the Lindemann ratio $c_L$ by $c_L^2 = < |u|^2 > / a_o^2$, we find that $c_L \approx 0.25$ for YBCO at $H_p = 5$ T and that $c_L \approx 0.11$ for BSCCO at $H_p = 200$ G. Here we have used the same values of the parameters that were used to fit the phase transition curves in Figure 1. These values of $c_L$ are consistent with previous values [11,12].

Experiments have found little, if any, hysteresis [13,14,15]. This is consistent with our calculations. We can bound the hysteresis by noting the range of temperatures between which the soft solid minimum appears and the solid minimum disappears. Typical values for the width of this temperature range are 300 mK for YBCO at $H = 5$ T and 1.3 K for BSCCO at $H = 200$ G. Another measure of the hysteresis can be found in the plots of $\Delta f$ versus $n$. The barrier height $V_B$ between the minima is low ($V_B v_o \sim 30$ mK) which is consistent with minimal hysteresis.

In going from the normal metallic phase to the vortex solid, two symmetries are broken: translational invariance and gauge symmetry which produces the superconducting phase coherence along the magnetic field. In the soft solid phase, longitudinal superconductivity is destroyed by the wandering of the defect lines which become entangled with the soft solid vortices. (A vortex solid with entangled vortex lines has been termed a supersolid [11,12] ) Even though line wandering is energetically costly and therefore rare, it does occur. As a result, the correlation length along the c–axis will be quite long. This is consistent with measurements in YBCO of the c–axis resistivity which find that there is loss of vortex velocity correlations for samples thicker than 100 $\mu$m [16]. For samples thicker than the longitudinal correlation length, the loss of longitudinal superconductivity coincides with the premelting transition [25]. This agrees with experiments which indicate that the loss of superconducting phase coherence along the c–axis coincides with the first order transition [22,23].

Since the soft solid is a lattice with a few percent of defect lines, the Fourier transform of the density-density correlation function should exhibit Bragg peaks. Relative to the ordinary vortex solid, the intensity of these peaks would be slightly diminished by the defect lines, so it would be difficult to detect the transition via neutron scattering. In going from the solid to the normal metallic state, translational invariance is regained by a first order melting transition. Thus there are two transitions: the premelting transition and the melting of the soft solid. Melting is observable in small angle neutron scattering experiments [27] which see a rapid decrease in the intensity of the Bragg spots. The region of the phase diagram where the soft solid exists may be quite narrow, of order a degree or less in temperature [26]. There is the intriguing possibility that our scenario of two transitions may be related to the peak effect in which the critical current as a function of temperature or field is observed to sharply increase below the melting transition [23]. This increase is believed to result from the enhanced pinning of flux lines due to the softening of the shear modulus $c_{66}$ [27].

To summarize we have discussed the possibility that a vortex lattice melts into a soft solid followed by another first order phase transition into a liquid. The premelting transition is induced by vacancy and interstitial vortex lines that soften the shear modulus and enhance the vibrational entropy. The entanglement of these defect lines with the vortex lines of the soft solid leads to the loss of longitudinal superconducting phase coherence. However, the correlation length corresponding to longitudinal superconductivity is quite long because line wandering is energetically costly and therefore rare. We obtain good agreement with the experimentally measured curve of transition temperature versus field, latent heat, and jumps in magnetization for BSCCO and YBCO. The Lindemann ratio $c_L$ is $\sim 11\%$ for BSCCO and $\sim 25\%$ for YBCO. The hysteresis is small.

We thank Andy Granato, Marty Maley, Lev Bu- laevskii, Sue Coppersmith, and David Nelson for helpful discussions. This work was supported in part by ONR grant N00014-96-1-0905 and by funds provided by the University of California for the conduct of discretionary research by Los Alamos National Laboratory. HMC acknowledges support by the Swiss Nationalfonds.

FIG. 1. First order phase transition curves of magnetic field versus temperature. for YBCO and BSCCO. Parameters used for YBCO are $\alpha_1 = 2.55$, $\alpha_2 = 0.01485$, $\phi = 44.1^\circ$, $\phi_0 = 1186 \text{A}$, $s = 12 \text{A}$, $\xi_{ab}(0) = 15 \text{A}$, $\gamma = 5$, and $T_C = 92.74 \text{K}$. Parameters used for BSCCO are $\alpha_1 = 1.0$, $\alpha_2 = 0.00705$, $\phi = 60^\circ$, $\phi_0 = 2000 \text{A}$, $s = 14 \text{A}$, $\xi_{ab}(0) = 37 \text{A}$, $\gamma = 200$, and $T_C = 90 \text{K}$. For BSCCO we use the low field form of the elastic moduli from (2), and for BSCCO we use the high field form. For $f_o$ we use (1) for BSCCO and (2) for YBCO. (For BSCCO we plot $B$ vs. $T$ because that is what ref. [7] measured.) The experimental points for YBCO come from ref. [3] and those for BSCCO come from ref. [3]. Inset: Typical $\Delta f$ versus $n$.

FIG. 2. (a) and (b): Entropy jump $\Delta s$ per vortex per layer versus $T_p$ at the transition for YBCO and BSCCO. The experimental points for YBCO are from (1) and those for BSCCO are from (2). (c) and (d): Magnetization jump $\Delta M$ versus $T_p$ at the first order phase transition for YBCO and BSCCO. The experimental points for YBCO are from (3) and those for BSCCO are from (4). For the theoretical points the values of the parameters are the same as in Figure 1 for all the curves.
