ABSTRACT

Aims. To understand the fundamental physical processes important for the evolution of solar rotation and
distribution of chemical species, we provide theoretical predictions for particle mixing and momentum
transport in the stably stratified tachocline.

Methods. By envisioning that turbulence is driven in the tachocline, we compute the amplitude of turbulent
flow, turbulent particle diffusivities, and eddy viscosity, by incorporating the effect of a strong radial
differential rotation and stable stratification. We identify the different roles that the shear flow and stable
stratification play in turbulence regulation and transport.

Results. Particle transport is found to be severely quenched due to stable stratification as well as radial
differential rotation, especially in the radial direction with an effectively more efficient horizontal transport.
The eddy viscosity is shown to become negative for parameter values typical of the tachocline, suggesting
that turbulence in the stably stratified tachocline leads to a non-uniform radial differential rotation. Similar
results also hold in the radiative interiors of stars, in general.

Key words. Turbulence – Sun: interior – Sun: rotation – waves

1. Introduction

Since the formation of the radiative core, which marked the beginning of its journey on the
main sequence, the sun has slowed down significantly due to the loss of angular momentum
from its surface (e.g. see Stix 1989; Schatzman 1993). The angular momentum transport must
have been very efficient during its spin-down in order for the sun to have rotational profile as
observed today (see, e.g. Charbonneau et al 1998). Vigorous turbulence in the convection zone and possibly thermal wind (Miesch, Brun & Toomre 2006) can readily provide a mechanism for efficient radial momentum transport, thereby eradicating radial differential rotation therein. Such turbulent transport is however considered to be absent in the stably stratified radiative interior, which has also spun-down during the solar evolution, presently rotating uniformly at the rate roughly the same as the mean average rotation rate on the solar surface. Whichever mechanism is responsible for momentum transport in the interior (which itself is an important problem), it should be closely related to the transport in the tachocline through which the surface spin-down is communicated to the interior. Transport in the tachocline also plays a crucial role in the overall mixing of light elements (lithium, beryllium, etc) (see e.g. Schatzman 1993; Brun, Turck-Chièze, & Zahn 1999), thereby determining the level of their surface abundances on the sun. Therefore, it is essential to understand physical mechanisms for transport in the tachocline and then to formulate a consistent theory starting from first principles based on those processes. This is particularly true since virtually all the previous theoretical modelling heavily relies on a simple parameterization of transport process, which is then adjusted to obtain the agreement with observations.

We have initiated the development of a consistent theory of turbulent transport in the tachocline in the previous papers, by taking into account the crucial effect of the large-scale shear flows, provided by a strong radial differential rotation (Kim 2005) as well as latitudinal differential rotation (Leprovost & Kim 2006). By envisioning that the tachocline is perturbed externally [e.g. by plumes penetrating from the convection zone above (e.g. see Gilman 2000; Brummell, Clune & Toomre 2002; Rogers & Glazmaier 2005)], or by instabilities (e.g. see Watson 1981; Charbonneau, Dikpati & Gilman 1999), we demonstrated how turbulence level and transport are reduced via shearing in a non-trivial manner (see also Burrell 1997; Kim & Diamond 2003; Kim 2004; 2006) in a simplified three dimensional (3D) hydrodynamic turbulence. In particular, turbulent transport of chemical species and angular momentum are shown to become strongly anisotropic with effectively much more efficient transport in the horizontal (latitudinal) direction than the vertical (radial) direction due to shear stabilization by strong radial shear. The resulting anisotropic momentum transport was shown to reinforce a strong radial shear (Leprovost & Kim 2006), with a positive feedback on the confinement of the tachocline (Spiegel & Zahn 1992) while chemical species are predicted to have latitudinal dependent mixing due to the variation of radial shear (Kim 2005). Furthermore, the results indicate that the turbulence regulation by a shear flow (i.e. differential rotation) leads to weak turbulence and mixing in turbulent tachocline.

The purpose of this paper is to investigate how a stable stratification in the tachocline modifies the predictions obtained in these studies. We again envision that the tachocline is turbulent, driven by a forcing as in Kim (2005). In the presence of a stable stratification, the turbulence in the tachocline is no longer completely random as the stable stratification provides a restoring force against radial displacement of fluid elements, supporting the propagation of internal gravity waves (Lighthill 1978). These waves tend to increase the memory of otherwise random turbulent
fluid motion and can reduce the overall transport due to turbulence. We shall show that the turbulent transport due to shear stabilization found in the previous studies is further enhanced in the presence of stable stratification (gravity waves). Thus, gravity waves acting together with shear stabilization can lead to a weak mixing in the tachocline, as required for the surface depletion of lithiums (e.g. Pinsonneault et al. 1989).

It is important to contrast our approach to those adopted in most previous works, which focus on the momentum transport by gravity waves themselves through dissipative processes (e.g. Plumb 1978; Kim and MacGregor 2001;2003; Talon, Kumar & Zahn 2002). For instance, gravity waves are considered to be generated in the convection zone (Press 1981) and deposit their momentum into background shear flow via radiative damping as they propagate through the tachocline and the interior (Kim and MacGregor 2001;2003). Relying crucially on radiative damping, the momentum transport by gravity waves would occur on a long time scale. [Recall that the transport by waves requires molecular dissipation, and is thus a slow process.] Similarly, weak mixing due to damped gravity waves was also suggested as a mechanism for a modestly enhanced mixing of light elements (lithium) (Press & Rybicki 1981; García López & Spruit 1991). In these works, a certain level of background turbulence could not be ruled out and was invoked to provide an enhanced viscosity for the evolution of a mean flow (Kim and MacGregor 2001;2003) and the gravity waves (Charbonnel & Talon 2005; Talon, Kumar & Zahn 2002). The value of the effective viscosity is often arbitrarily taken to be a positive constant, being much larger than molecular viscosity, not affected by shear flow nor by gravity waves, or it is simply parameterized.

In this paper, we shall treat turbulence and gravity waves on an equal footing and consistently compute the values of turbulent eddy viscosity and particle diffusivity, by incorporating the effect of a shear flow (provided by a radial differential rotation), and identify different roles that gravity waves and shear flow play in turbulent transport. Specifically, we shall show that unlike shear flows, which reduce both turbulence level and transport, a stable stratification can suppresses turbulent transport without much effect on turbulence level. We shall further demonstrate that the stratification favors a negative eddy viscosity and thus tends to sharpen the radial gradient of large-scale shear flows rather than smoothing it out. This tendency was also found in Kim & MacGregor (2001;2003). We note that the elucidation of the effects of gravity waves is essential for understanding the momentum transport in the radiative interior as they have often been advocated as a mechanism to explain a uniform rotation in that region. Stratified turbulence with a shear flow is also important for the transport in radiative interiors and/or envelopes of stars, in general, as well as in geophysical systems. In particular, it has actively been studied in geophysical systems (e.g. see Jacobitz, Sarkar & van Atta 1997; Stacey, Monismith, & Burau 1999), where stable stratification was shown to inhibit turbulent transport in the direction of a background density gradient, leading to the two dimensional (2D) turbulence.

The remainder of the paper is structured as follows. We first investigate the effect of gravity waves on turbulence in Sect. 2. In Sect. 3, we incorporate the effect of strong radial differential rotation.
tial rotation and study how the gravity waves modify the overall turbulent transport. Section 4 contains the conclusion and discussions.

2. Internal Gravity Waves

To simplify the problem, we shall consider incompressible fluid with local cartesian coordinates $x, y,$ and $z$ for radial, azimuthal, and latitudinal directions, respectively (see Fig. 1), and use Boussinesq approximation to capture the effect of stratification. We assume that the fluid is stirred by a forcing on small scales, giving rise to fluctuations. In the absence of stratification, this fluid forcing will drive turbulence on small scales and maintain it at the level at which the injected energy is balanced by dissipation in the system. As the stratification increases, the forcing will generate not only random turbulent motion but also coherent (gravity) waves. Alternatively, some of turbulent motion will be turned into packets of gravity waves. Therefore, we consider both turbulence and gravity waves as fluctuations on scales much smaller than those associated with mean density or mean background shear flows. Specifically, we express the total mass density $\rho = \rho_0(x) + \rho'$ where $\rho_0(x)$ and $\rho'$ are the background and fluctuating mass densities, respectively; the total velocity $u = U_0 + v$ where $U_0$ and $v$ are a large-scale shear flow due to differential rotation and small-scale fluctuations; the total particle density of chemical elements $n = n_0(x) + n'$ where $n_0(x)$ and $n'$ are mean and fluctuating components. Then, the main governing equations for fluctuations $v, \rho'$, and $n'$, involving both turbulence and gravity waves, are as follows (see, e.g., Kim & MacGregor 2003; Moffatt 1978):

$$\begin{align*}
(\partial_t + U_0 \cdot \nabla) v &= -\nabla p - g \rho' \hat{x} + \nu \nabla^2 v + f, \\
\nabla \cdot v &= 0, \\
(\partial_t + U_0 \cdot \nabla) \rho' &= \frac{\nu N^2}{g} v_z + \mu \nabla^2 \rho', \\
(\partial_t + U_0 \cdot \nabla) n' &= -\partial_z n_0 v_z + D \nabla^2 n'.
\end{align*}$$

Here, $\nu$, $\mu$, and $D$ are molecular viscosity, thermal diffusivity, and particle diffusivity, respectively; $f$ in Eq. (1) is the small-scale forcing driving turbulence; $\rho_0 = \rho_0(x = 0)$ is the constant background density [measured at the bottom of the convection zone (e.g. see Kim and MacGregor 2003)], and $N = \sqrt{-g(\partial_x \rho_0 + \frac{\rho g}{\rho_0 c_s^2})/\rho}$ is the Brunt-Väisälä frequency, where $c_s$ is the sound speed. Note

Fig. 1. The configuration of our model.
that the typical values of $v$, $D$, $\mu$, and $N$ in the tachocline are $10^2 \text{ cm}^2 \text{s}^{-1}$, $10^2 \text{ cm}^2 \text{s}^{-1}$, $10^7 \text{ cm}^2 \text{s}^{-1}$, and $3 \times 10^{-3} \text{ s}^{-1}$, respectively.

In this section, we first ignore a background shear flow and study how the turbulence and transport are modified due to stable stratification in the tachocline. To obtain the overall turbulent transport, we solve coupled equations (1)-(4) in terms of Fourier transform for fluctuating quantities $\phi'$:

$$\phi'(x, t) = \frac{1}{(2\pi)^3} \int d^3k \tilde{\phi}(k, t) \exp\{i(k_x x + k_y y + k_z z)\}. \quad (5)$$

Equations (1)-(3) then give us an equation for $\tilde{\rho} = e^{itf} \tilde{\rho}$ in the form

$$\partial_t \tilde{\rho} + (\mu - \nu) k^2 \tilde{\rho} + N^2 \tilde{\rho} = \frac{N^2}{g} e^{ikz} \tilde{h}_1. \quad (6)$$

Here, $N^2 = \gamma N^2/(\gamma + a^2)$. Since $N \gg \mu k^2$ is valid on a broad range of reasonable scales $l \gg 10^4 \sim 10^5 \text{ cm}$ in the tachocline, we can find the solutions to leading order in $(\nu k^2/N \ll \mu k^2/N \ll 1$ as:

$$\tilde{v}_x \sim \frac{1}{\gamma + a^2} \int dt' G_\mu(t, t') \cos N(t - t') \tilde{h}_1(t'),$$

$$\tilde{v}_y \sim \frac{\alpha}{\gamma} \tilde{v}_x - \frac{\beta}{\gamma} \int dt' G(t, t') \tilde{h}_2(t'),$$

$$\tilde{v}_z \sim -\frac{\alpha \beta}{\gamma} \tilde{v}_x + \frac{1}{\gamma} \int dt' G(t, t') \tilde{h}_2(t'),$$

$$\tilde{\rho} \sim \frac{N}{g \sqrt{\gamma(\gamma + a^2)}} \int dt' G_\mu(t, t') \sin N(t - t') \tilde{h}_1(t'). \quad (10)$$

Here, $G(t, t') = e^{-\nu k^2(t-t')}$ and $G_\mu(t, t') = e^{-(\nu k^2+\mu k^2(t-t')/2)}$ are the Green’s functions; $a = k_x/k_y$, $\beta = k_z/k_y$, and $\gamma = 1 + \beta^2$; $\tilde{h}_1$ and $\tilde{h}_2$ in Eqs. (6) and (7)-(10) are the forcing terms which are related to $\tilde{f}$ as

$$\tilde{h}_1 = (1 + \beta^2) \tilde{f}_x - a \tilde{f}_y - a \beta \tilde{f}_z,$$

$$\tilde{h}_2 = -\beta \tilde{f}_y + \tilde{f}_z. \quad (12)$$

Equations (7)-(9) show that the vertical motion $\tilde{v}_z$, involving $G_\mu$ only, is always subject to radiative damping $\mu$ while the horizontal motions $\tilde{v}_y$ and $\tilde{v}_x$, containing both $G_\mu$ and $G$, are much less affected by $\mu$.

For simplicity, we assume the forcing to be homogeneous in space with a short correlation time $\tau_f$:

$$\langle \tilde{f}(k_1, t_1) \tilde{f}(k_2, t_2) \rangle = \tau_f (2\pi)^3 \delta(t_1 - t_2) \delta(k_1 + k_2) \psi_{ij}(k_2). \quad (13)$$

Note that in the case where the forcing $f$ due to plumes induces a stronger turbulence towards the bottom of the convection zone, $f$ becomes inhomogeneous with the power spectrum $\psi_{ij} = \psi_{ij}(x, k)$ depending on the radial coordinate $x$.

A long but straightforward algebra by using Eqs. (7)-(13) then gives us the following results on turbulence level and particle diffusivities defined by $\langle n'v_i \rangle = -D_{ij}^{ij} \partial_j n_0$:..
Here, we assumed spatial symmetries $\phi_{ij}(k_y) = \phi_{ij}(-k_y)$ and $\phi_{ij}(k_z) = \phi_{ij}(-k_z)$; $k$ inside the integrals in Eqs. (14)-(19) is the wavenumber of the forcing; $\phi_{ij}(k) (i = 1, 2)$ is the power spectrum of the forcing defined by:

$$
\langle \hat{h}_i(k_1, t_1) \hat{h}_j(k_2, t_2) \rangle = \tau_f (2\pi)^3 \delta(t_1 - t_2) \delta(k_1 + k_2) \phi_{ij}(k_2).
$$

(20)

In this paper, we shall consider an incompressible forcing ($\nabla \cdot \mathbf{f} = 0$) for simplicity, in which case $\phi_{ij}$ in Eq. (20) is related to $\psi_{ij}$ in Eq. (13) as:

$$
\phi_{11} = \frac{k^4}{k_y} \psi_{11}, \quad \phi_{12} = \frac{1}{k_y^2}(k^2 k_y \psi_{11} + k^2 k_{1H} \psi_{13}),
$$

$$
\phi_{22} = \frac{1}{k_y^2}(k^2 k_y^2 \psi_{11} + k_{1H}^2 \psi_{33} + 2k_y k_{1H}^2 \psi_{13}).
$$

(21)

Note that $\phi_{11}$ and $\phi_{22}$ can signify strong radial forcing (e.g. by plumes) and horizontal forcing [e.g. due to the instability of the latitudinal shear in the tachocline (see also Kim 2005)]. For instance, in the case of strong radial forcing by plumes ($\psi_{11} \gg \psi_{33}$) with $k_{1H} \gg k_z$ (see Fig. 2 in Leprovost & Kim 2006), $\phi_{11}$ will dominate over $\phi_{22}$. Note further that in the 2D limit with $k_z = 0$ and $\psi_{33} = 0$, $\phi_{22}$ vanishes.

We discuss some of the important implications of Eqs. (14)-(19). First, all three components of fluctuating velocity amplitude in Eqs. (14)-(16) are independent of $N$, clearly showing that the amplitude of the turbulent flow is not influenced by stable stratification in the case of the forcing with a short correlation time. The exact level of fluctuations is determined by the characteristics of the external forcing ($\phi_{ij}$). We examine this in the simple 2D limit where $k_z = 0 (\gamma = 1)$ and $\psi_{33} = 0$. In this limit, the substitution of $\phi_{22} = 0$ in Eqs. (14)-(16) gives $\langle v_x^2 \rangle / \langle v_2^2 \rangle \sim 1/a^2 = k_y^2/k_z^2$ and $\langle v_2^2 \rangle = 0$. This is an expected result for the 2D incompressible fluid in $x - y$ domain. If the forcing $f$ contains only gravity modes, the wave number of the forcing would satisfy the local dispersion relation $k_x = \pm k_y \sqrt{N^2/\omega - U_0 k_y^2} - 1$ (here, $\omega$ is the frequency of the gravity waves).

Furthermore, if these gravity modes are generated by the overturning of fluids in the convection zone (e.g. Press 1981) with $U_0 \sim 0$, they would have a strong power at low frequencies $\omega \ll N$, thereby giving $k_x/k_y \sim N/\omega \gg 1$, and thus $\langle v_x^2 \rangle / \langle v_2^2 \rangle \ll 1$. Note that this is the situation
normally considered in the previous works (e.g. Kim & MacGregor 2001;2003; Talon, Kumar & Zahn 2002), where the main focus was on the momentum deposition by such gravity waves due to radiative damping after entering the tachocline from the bottom of the convection zone. In contrast, in this paper, the forcing $\mathbf{f}$ is not restricted to gravity modes, but is taken to be general, including any form of perturbation with arbitrary values of $k_x/k_y$. For instance, in the case of a strong radial forcing due to plumes with $\phi_{11} \gg \phi_{22}$ and $a = k_x/k_y \ll 1$ (see Fig 2 in Leprovost & Kim 2006), $\langle \nu_x^2 \rangle / \langle \nu_y^2 \rangle \gg 1$ with a stronger radial fluctuation than horizontal one. Furthermore, Eqs. (14)-(16) show that the level of anisotropy measured by the ratio of the turbulence amplitude depends on $\nu$ and $\mu$. For instance, for an isotropic forcing with $\phi_{11} \sim \phi_{22}$, $\langle \nu_x^2 \rangle / \langle \nu_y^2 \rangle \propto \nu/\mu \ll 1$ becomes small as the radiative damping $\mu$ increases. This is because a large $\mu$ tends to decrease (vertical) turbulence level by introducing large (thermal) dissipation. Thus, without a shear flow, a stronger horizontal turbulence (level) than vertical one can be caused by large thermal diffusivity $\mu$ (but not by stratification) in the case of a temporally short correlation forcing. Note that the anisotropy in turbulence level could be related to the Peclet number $Pe = vl/\mu$ as $\langle \nu_x^2 \rangle / \langle \nu_y^2 \rangle \propto Pe$. Here, $v$ and $l$ are the characteristic velocity and length scale of the forcing (which is fixed).

Second, turbulent transport in Eqs. (17)-(19) are strongly affected by stratification as $N^2$ increases, in contrast to fluctuation levels in Eqs. (14)-(16). Since $N \gg \mu k^2$ on reasonable scales $l \gg 10^4 \sim 10^5$ cm, the vertical (radial) mixing is severely quenched as the stratification increases (i.e. as $N^{-2}$), in qualitative agreement with Brun, Turck-chièze & Zahn (1999). In comparison, the part of the horizontal (latitudinal) mixing due to the radial forcing $\phi_{11}$ is reduced proportional to $N^{-2}$ while the one due to the horizontal forcing $\phi_{22}$ is independent of $N$. The comparison of these two contributions (or alternatively $D_{xx}$ and $D_{yy}$) in the case of $\phi_{11} \sim \phi_{22}$ gives us a cut-off scale $l_c \sim \sqrt{v/N}$ above which vertical (radial) mixing is strongly reduced compared to the horizontal (latitudinal) mixing. That is, in the presence of both radial and horizontal forcings of comparable strength, stable stratification mainly reduces the vertical transport without much effect on horizontal transport on scales $l > l_c$. For parameter values typical of the tachocline $v \sim 10^2$ cm$^2$s$^{-1}$ and $N \sim 3 \times 10^{-3}$s$^{-1}$, $l_c \sim 10^2$cm. Thus, the stratification is very likely to play an important role over a broad range of physically reasonable scales. In the limit of strong radial forcing with $\phi_{11} \gg \phi_{22}$ and $a \sim 0$, the stratification influences both the radial and horizontal transports to the same degree while the incompressibility renders $D_{xx}^r / D_{rr}^r \sim D_{yy}^r / D_{rr}^r \sim 1/a^2 \sim \langle \nu_x^2 \rangle / \langle \nu_y^2 \rangle \gg 1$, with an effectively more efficient radial transport. It is interesting to compare our result $D_{xx} \propto N^{-2}$ with the mixing due to radiatively damped waves (e.g. García López and Spruit 1991; Talon et al 2002). For instance, García López and Spruit (1991) estimated the vertical mixing due to gravity waves to be proportional to $\mu/N^2$. While the reduction in vertical mixing for large $N$ is in qualitative agreement with our results ($\propto N^{-2}$), the increase in vertical mixing in García López and Spruit (1991) is due to the fact that damped waves are necessary for wave transport. Finally, we note that without a shear flow, momentum transport vanishes (i.e. $\langle v_x v_y \rangle = \langle v_y v_x \rangle = 0$) for an isotropic forcing. Scaling of turbulence amplitude, turbulent viscosity ($\nu_T$), and turbulent diffusivity $D_T$ are summarised in Table 1 for an isotropic forcing.
A large thermal diffusivity ($\mu = 10^5 \nu$) in the tachocline is often considered to reduce the stabilizing effect of stable stratification via the weakening of the buoyancy restoring force. To highlight this effect, it is illuminating to consider the extreme limit of strong thermal diffusion where density fluctuation becomes stationary with $\partial_t \rho' = N^2 v_s / g - \mu k^2 \rho' = 0$ in Eq. (3). In this limit, by following a similar analysis as previously (with $D = \nu$), we can easily obtain the vertical and horizontal particle diffusivities as follows:

\begin{align}
D_{xx} \sim & \frac{\tau_f}{2\alpha} \int \frac{d^3 k}{(2\pi)^3 (\gamma + a^2)^2} \phi_{11}(k), \\
D_{yy} \sim & \frac{\tau_f}{2\alpha} \int \frac{d^3 k}{(2\pi)^3 (\gamma + a^2)^2} \left[ \frac{a^2 \phi_{11}(k)}{\gamma^2 (\gamma + a^2)^2} \frac{1}{2\alpha^2} + \frac{\beta^2 \phi_{22}(k)}{(2\nu k^2)} \right],
\end{align}

where $\alpha = \gamma N^2 / \mu k^2 (\gamma + a^2)$. Equation (22) shows that the vertical mixing $D_{xx} \propto \mu^2 / N^4 \propto Pe^{-2}$ decreases for large $N$ while increasing for large $\mu$. This is because the reduction in the vertical mixing due to buoyancy force is weaken by a strong radiative damping $\mu$. The comparison of Eqs. (22)-(23) further shows that the reduction in vertical mixing relative to horizontal mixing is given by a factor of $(\nu k^2)^2 / \alpha^2$ for an isotropic forcing and is thus weaker than that in the case of weak radiative damping $\mu k^2 \ll N$ [see Eqs. (17)-(19)]. Furthermore, this reduction appears on scales larger than the critical scale $l_{in} = (\mu \nu)^{1/4} / N^{1/2} \sim 10 l_c$. Here, $l_c = \sqrt{\nu/N}$ is the critical scale in the case of $\mu k^2 \ll N$. These results thus show that a strong thermal diffusion weakens the buoyancy effect and makes the effect of stratification become important on larger scales, compared to the case of a weak thermal diffusion. This result is thus consistent with the expectation employed in previous works.

To summarize, a stable stratification can dramatically quench turbulent transport with a more effective mixing in the horizontal directions orthogonal to the background density gradient. It does not however affect the amplitude of the turbulent flow, the ratio of which is found to depend only on $\nu/\mu$ (for a temporally short-correlated forcing).

### 3. Consistent theory

The results in Sec. 2 showed that for a temporally short correlated forcing, a stable stratification reduces turbulent transport only, leading to anisotropic turbulent transport, without much effect on turbulence level. In this section, we study how these results are modified by a stable background shear flow (differential rotation in the tachocline). In particular, we will show that a shear flow not only inhibits the vertical mixing further, enhancing the anisotropic transport, but also reduces turbulence levels anisotropically, thereby leading to effectively stronger horizontal turbulence. For simplicity, we ignore the latitudinal differential rotation compared with the radial differential rotation since it is weaker in the tachocline due to thin tachocline ($h < 0.03 \sim 0.05$ of the solar radius $R$). The inclusion of the latitudinal differential rotation would introduce a small correction term in our results. For instance, for turbulence amplitude, this correction term is of order $(h/R)^2 \ll 1$, as shown in Leprovost and Kim (2006). Note that the latitudinal shear is crucial for non-vanishing horizontal momentum transport in Leprovost & Kim (2006). Again,
we envision that turbulence is maintained in the tachocline by an external forcing while gravity waves are excited due to this external forcing in the stably stratified tachocline. We shall then compute the overall turbulent transport consistently by taking into account the interaction among turbulence, shear flow and gravity waves, instead of simply assuming a (large) constant value of turbulent viscosity for mean shear flow (and gravity waves). Note that this treatment is essential when there is no clear scale separation between gravity waves and turbulence, in which case turbulence cannot be considered to give an enhanced value of viscosity for gravity waves (c.f. Charbonnel & Talon 2005).

For the evolution of fluctuations, we approximate the radial differential rotation by a linear shear flow with \( U_0 = -x\hat{A}\hat{y} \) to keep the analysis tractable. Here, \( \hat{A} \) is the shearing rate which we assume to be positive without loss of generality. As done in previous papers (Kim 2005; Leprovost & Kim 2006), to capture the effect of shearing due to radial differential rotation (\( \hat{A} \sim 3 \times 10^{-6} \) s\(^{-1} \) for the tachocline) non-perturbatively, we use the special Fourier transform for fluctuating quantities \( \phi' \):

\[
\phi'(x, t) = \frac{1}{(2\pi)^3} \int d^3 k \tilde{\phi}(k, t) \exp\left[ i(k_x(t)x + k_y y + k_z z) \right].
\]  

(24)

Here, \( k_x = k_x(t) \) is the time dependent [unlike constant \( k_x \) in Eq. (5)], satisfying an eikonal equation

\[
\partial_t k_x(t) = k_y \hat{A}.
\]  

(25)
Equation (25) implies that $k_z$ linearly increases in time as $k_z(t) = k_z(0) + k_z\Delta t$, manifesting the main effect of shearing by a shear flow $U_0(x)\hat{y}$, i.e., generation of fine scales in the $x$ direction due to tilting and distortion of fluid eddies (e.g. see Burrell 1997; Kim 2004; Kim 2005). The efficient generation of fine scales by shearing leads to the breakup of eddies and enhancement of the overall dissipation, thereby reducing turbulence amplitude and transport (e.g. see Kim 2005). A similar effect by a shear flow is expected to persist for a more realistic radial shear [e.g. for an error function used in helioseismic inversions (Kosovichev 1996; Corbard et al 1999)] since the basic mechanism of shearing (e.g. see Fig. 2 in Kim 2005) is the same regardless of the details of the profile of radial shear. The efficiency of the shearing could depend on the details of the profile, possibly leading to a slightly different scaling.

It is interesting to note that a gravity wave with an initially positive value of $k_z(0)$ can change its sign after the time interval $k_z(0)/k_z\Delta t$ (for $k_z > 0$) due to shearing. Since the local (radial) group velocity of gravity waves is given by $v_{gx} = -k_z^2 k_z N^2/k_4 (\omega - U_0 k_y)$ (e.g., see Kim & MacGregor 2003), the gravity wave thus alters its propagation direction as $k_z$ flips its sign. Therefore, a gravity wave which initially propagates downward to the interior from the convection zone with a negative vertical group velocity (i.e. $v_{gx} < 0$) can propagate upwards when the vertical group velocity becomes positive ($v_{gx} > 0$) due to shearing.

For parameter values typical of the tachocline $N \sim 3 \times 10^{-3} \text{ s}^{-1}$ and $\mathcal{A} \sim 3 \times 10^{-6} \text{ s}^{-1}$, $Ri = N^2/\mathcal{A}^2 \gg R_i = 1/4$, satisfying the stability criterion (Lighthill 1978). We thus assume that the radial shear flow is stable with large value of $Ri = N^2/\mathcal{A}^2 \gg 1$ in the remainder of the paper (see also Schatzman, Zahn, & Morel 2000). Note that the buildup of chemical composition gradient (the so-called $\mu$ gradient in the solar interior [e.g. see Michaud and Zahn (1998) and references therein] would further increase the values of $N$ and $Ri$, making the radial shear flow more stable, although this effect could be counteracted by a radiative damping, as shown in Sec 2. The shearing rate $\mathcal{A} \sim 3 \times 10^{-6} \text{ s}^{-1}$ due to this radial differential rotation is larger than the dissipation rate due to radiative damping $\mu k_z^2$ on a broad range of scales $l = 1/k_z > 10^6 \sim 10^7 \text{ cm} \sim 10^{-3} H_0$, where $H_0$ is the pressure scale height $\sim 6 \times 10^9 \text{ cm}$. Thus, we focus on the strong shear limit in the following by using $\xi_\mu = \mu k_z^2/\mathcal{A} \ll 1$ as a small parameter.

For $Ri \gg 1$ and $\nu \sim D \ll \mu$, a long but straightforward algebra can give us the solutions to Eqs. (1)-(4), as shown in Appendix A. By using these solutions and the correlation functions of forcing defined in Eq. (20), we obtain the following results for turbulence level and transport coefficient defined by $(n'v_i) = -D_i^j \partial_j n_0$ for $i = 1, 2$ and 3, and momentum flux $(v_x v_y) = -v_x \partial_x U_0$ in the strong shear limit $\xi_\mu = \mu k_z^2/\mathcal{A} \ll 1$ (see Appendix A for details):

$$
\langle v_x^2 \rangle = \frac{\tau_f}{\mathcal{A}} \int \frac{d^3 k}{(2\pi)^3} \frac{\phi_{11}(k)}{2 \nu^{1/2}} ,
$$

$$
\langle v_y^2 \rangle = \frac{\tau_f}{\mathcal{A}} \int \frac{d^3 k}{(2\pi)^3} \left[ \frac{\phi_{11}(k)}{2 \nu^{3/2}} \ln \xi_\rho + \frac{\beta^2 \phi_{22}(k)}{\gamma^2} G_0 \right] ,
$$

$$
\langle v_z^2 \rangle = \frac{\tau_f}{\mathcal{A}} \int \frac{d^3 k}{(2\pi)^3} \left[ \frac{\beta^2 \phi_{11}(k)}{2 \nu^{3/2}} \ln \xi_\rho + \frac{\phi_{22}(k)}{\gamma^2} \right] ,
$$

where $\phi_{ij}(k)$ are the structure functions of forced turbulence.
\[
\begin{align*}
D_T^{ws} &= \frac{\tau_f}{2N^2} \int \frac{d^3k}{(2\pi)^3} \left[ \frac{1}{\sqrt{y+a}} \phi_{11}(k) \xi DG_1, \right. \\
D_T^{wy} &= \frac{\tau_f}{2} \int \frac{d^3k}{(2\pi)^3} \left[ \left( \frac{1}{\sqrt{y+a}} \phi_{11}(k) \xi D \frac{3}{2} \right) + \frac{\beta^2 \phi_{22}(k) \Gamma(\frac{3}{2})}{\mathcal{A}^2} \left( \frac{3}{2\xi_v} \right) \right], \\
\nu_T &= -\frac{\tau_f}{2} \int \frac{d^3k}{(2\pi)^3} \left[ \frac{1}{\sqrt{y+a}} \phi_{11}(k) \right] \left( \frac{1}{\mathcal{A}^2} + \frac{1}{12N^2(y+a)} \right). 
\end{align*}
\]

Here, \( \xi_v = v k_y^2 / \mathcal{A} \ll 1, \xi_D = D k_y^2 / \mathcal{A} \ll 1, \xi_\mu = \mu k_y^2 / \mathcal{A} \ll 1, \) \( G_1 = \frac{1}{4} \Gamma(1/3) (3/2 \xi_v)^{1/3} \) and \( G_1 = \frac{1}{4} \Gamma(1/3) (3/\xi_\mu)^{1/3} \). Note again that \( \xi_\mu \ll 1 \) is valid on a broad range of scales \( k(0/k_0) \gg 10^6 \sim 10^7 \) cm in the tachocline and also that \( \xi_v \ll 1 \) guarantees that \( \xi_D \sim \xi_v \ll 1 \) since \( D \sim v \ll \mu \). The spectrum \( \phi_{ij} \) in Eqs. (26)-(31) are given by Eqs. (20), which are related to power spectrum of forcing \( \psi_{ij} \) in Eq. (13) in the incompressible case.

Equations (26)-(31) reveal the following interesting features. Turbulence levels given in Eqs. (26)-(28) are again independent of stratification, similarly to the case without a shear flow [Eqs. (14)-(16)], while they are reduced for strong shear \( \mathcal{A} \). This indicates that waves and shear flows play different roles in turbulence regulation – waves do not necessarily quench fluctuation levels while shear flows can reduce them through enhanced dissipation via shearing. The turbulence regulation by shearing gives us horizontal velocity fluctuations in Eqs. (27) and (28) which are effectively higher than vertical one in Eq. (26). While a similar tendency was also found in the absence of gravity waves (Kim 2005), the exact value of the ratio of vertical to horizontal turbulence levels is not the same. For example, \( \langle v_y^2 / \langle v_y^2 \rangle \propto \langle v \rangle / \langle \ln \xi_\mu \rangle \rangle \) for a strong radial forcing \( \phi_{11} \) with \( \phi_{22} = 0 \) while \( \langle v_y^2 / \langle v_y^2 \rangle \propto \xi_v \rangle \) for an isotropic forcing with \( \phi_{11} \sim \phi_{22} \). Note that \( \xi_v \ll \xi_\mu \ll 1 \) are small parameters in our problem, representing the strong shear limit. These results are to be compared with \( \langle v_y^2 / \langle v_y^2 \rangle \propto \xi_v \rangle \) in the unstratified medium (Kim 2005). The results for the isotropic forcing in various cases are summarised and compared in Table 1.

Transport properties in Eqs. (29)-(31) however exhibit a very different behaviour, with both vertical and horizontal mixing being inhibited in a non-trivial manner by strong stratification as well as by shearing. First, the vertical transport is reduced as \( D_T^{ws} \propto \xi_\mu \xi_D^{-2/3} N^{-2} \propto D_\mu^{-2/3} \mathcal{A}^{-1/3} N^{-2} \), becoming small as either stratification or shearing increases. Note that the decrease in \( D_T^{ws} \) for large \( N \) agrees with Miesch (2003). Interestingly, \( D_T^{wy} \propto \mu^{-2/3} \propto Pe^{-2/3} \) decreases as the radiative damping \( \mu \) increases. This is because large radiative damping increases thermal dissipation, thereby mainly inhibiting the vertical mixing, as noted in Sec. 2. Thus, compared to the case with \( N = 0 \) where \( D_T^{ws} \propto \mathcal{A}^{-2} \) (Kim 2005), the vertical mixing is much more quenched by a factor of \( \xi_\mu \xi_D^{-2/3} \propto N^{-2} \) \( \xi_D \xi_\mu^{-2/3} = (D/\mu) \xi_\mu^{-1/3} \ll \xi_\mu \ll 1 \) since \( \mathcal{A}/N < 1 \) and \( D/\mu \sim 10^{-5} \) in the tachocline (see also Table 1). This clearly shows that shear flow (orthogonal to radial density gradient), stable stratification, and radiative damping can all inhibit the radial transport.

Second, \( D_T^{wy} \) is less affected by stratification since it involves the two parts – the one from \( \phi_{11} \) is proportional to \( \xi_\mu \xi_D^{-4/3} N^{-2} \) while the other from \( \phi_{22} \) is proportional to \( \mathcal{A}^{-2} \xi_\mu^{-2/3} \), independent of \( N \). In the simplest case of a strong radial forcing with \( \phi_{22} = 0, D_T^{wy} / D_T^{ws} \sim \xi_\mu^{-2/3} \ll 1 \), independent of \( N \). This is similar to the case without stratification where \( D_T^{wy} / D_T^{ws} \sim \xi_\mu^{-2/3} \) (Kim 2005). In
the general case where $\phi_{11} \neq 0$ and $\phi_{22} \neq 0$, $D_{T}^{22}$ exhibits a non-trivial, complex interplay among stratification and shear flow in determining the overall transport. To appreciate this, we compare Eq. (30) with the result obtained without shear flow (18) to find that shear flow enhances the stratification and shear flow in determining the overall transport. To see this, we compare the two contributions to $D_{T}^{22}$ from $\phi_{11}$ and $\phi_{22}$ separately to those in the case of $N = 0$ in Kim (2005), where $D_{T}^{22} \propto (A/N)^{2} \xi_{v}^{-2/3}$ from both $\phi_{11}$ and $\phi_{22}$. That is, the contribution from $\phi_{11}$ is further reduced by a factor of $(\nu/\beta)_{v}^{4/3} \nu/\mu \ll 1$, independent of $N$. This is analogous to the result $D_{T}^{22} \propto (A/N)^{2} \xi_{v}^{-2/3}$ obtained in the unstratified case (Kim 2005). In this case, the anisotropy in transport is solely caused by shear stabilization. For an isotropic forcing with $\phi_{11} \sim \phi_{22}$ and $a \sim 1$, $D_{T}^{22} / D_{T}^{22} \propto (A/N)^{2} (\nu/\mu)^{2/3} \xi_{v} \ll 1$. In other words, the anisotropy in turbulent transport depends on stratification, shear, and $\nu/\mu$, as clearly shown in Table 1. Since $(A/N)^{2} \ll 1$ and $\nu/\mu \ll 1$ in the tachocline, $D_{T}^{22} / D_{T}^{22}$ is much smaller than $\xi_{v}^{2/3}$ obtained in the unstratified case (Kim 2005). That is, the anisotropy in transport is further enhanced due to stratification. We emphasize that the anisotropy in turbulent transport is much stronger than that in turbulence amplitude, discussed previously (see also Table 1). This result also shows the reduction in $D_{T}^{22}$ for large $\mu$ and again highlights the importance of the radiative damping in reducing the vertical transport, thereby increasing the anisotropy in the transport.

Finally, Eq. (31) demonstrates one of the most important effects of a stable stratification, which is to drive a system away from a uniform rotation with a negative eddy viscosity. Recall that in the absence of stratification the eddy viscosity is positive in 3D while negative in 2D limit (e.g. see Kim 2005). In contrast, the eddy viscosity in Eq. (31) is negative in both 2D ($\beta = 0$ and $\gamma = 1$) and 3D cases. This behavior was also found in recent numerical simulation by Miesch (2003) of a stably stratified turbulence with an imposed shear driven by penetrative convection, who found anti-diffusive radial and diffusive latitudinal momentum transport, thereby offering a mechanism for a proper transition from latitudinal differential rotation in the convection zone to solid body rotation in the radiative interior. Anti-diffusive momentum transport is a generic feature of a strongly stratified medium (i.e. a geophysical system). It is interesting to note that a negative viscosity was also found in the previous work on momentum transport due to radiatively
damped gravity waves (e.g. Kim and MacGregor 2001;2003). In addition, the result \(^{(31)}\) shows that the (anti-diffusive) momentum transport becomes less efficient for strong stratification (large \(N\)), in agreement with Miesch (2003).

To summarise, our results show that the shearing effect by radial differential rotation together with gravity waves is an important mechanism for turbulence regulation, leading to a weak turbulent transport and anisotropic turbulence and transport in the tachocline. Furthermore, we have consistently derived the values of turbulence level, particle mixing and momentum transport starting from the first principle, clearly identifying the different roles of gravity waves and shearing in transport. For instance, in comparison with Chaboyer and Zahn (1992) [or Spiegel and Zahn (1992)] which start with the assumption of a strong horizontal mixing, we identified the source of such an anisotropic turbulence. In particular, we have made a clear distinction between the anisotropy in the turbulence level and turbulent transport.

4. Discussion and conclusions

We have studied turbulent transport in the stably stratified tachocline with a strong radial differential rotation, when turbulence is driven and maintained by a forcing (e.g. due to plumes penetrating from the convection zone or due to instability). We have assumed that both turbulence and gravity waves are on small scales (with no clear scale separation between the two) and treated the interaction among gravity waves, turbulence and shear flow consistently. Unlike a shear flow which regulates both turbulence level and transport, a stable stratification is shown to mainly inhibit turbulent transport, leading to a further reduction in transport compared to the unstratified case (Kim 2005). Specifically, for parameter values typical of the tachocline \((N/\mathcal{A} \gg 1)\), particle transport due to a strong radial forcing \(\phi_{11}\) (with \(\phi_{22} = 0\)) is reduced as \(\xi_D \xi_{\mu}^{-2/3} N^{-2}\), becoming much smaller than horizontal transport \((\propto \xi_D \xi_{\mu}^{-4/3} N^{-2})\) by a factor of \(\xi_{\mu}^{2/3} \ll 1\). Here, \(\xi_v = v k_x^2 / \mathcal{A} \ll 1\), \(\xi_D = D k_y^2 / \mathcal{A} \ll 1\), and \(\xi_{\mu} = \mu k_y^2 / \mathcal{A} \ll \xi_v\) are the small parameters characterizing a strong shear limit (see the main text for more details). Note that in this case \(D_T^{xx} / D_T^{yy} \propto \xi_{\mu}^{2/3} \ll 1\) depends only on shearing but not on stratification, indicating that the anisotropy in particle transport is mainly governed by radial differential rotation. A similar scaling \((\propto \xi_v^{2/3} \ll 1)\) was also found in the unstratified case (Kim 2005). However, in the case of an isotropic forcing with \(\phi_{11} \sim \phi_{22}\) and \(k_x/k_y \sim 1\), the horizontal mixing is much less reduced with \(D_T^{xx} \sim \mathcal{A}^{-2} \xi_v^{2/3}\) (with no effect of stratification), leading to a stronger anisotropy in transport with \(D_T^{xx} / D_T^{yy} \sim (\mathcal{A}/N)^2 (\nu/\mu)^{2/3} \xi_v \ll \xi_v^{2/3} \ll 1\). Note that the anisotropy becomes stronger for larger \(\mu\).

Furthermore, the vertical momentum transport was shown to be anti-diffusive with a negative eddy viscosity. That is, small-scale turbulence influenced by gravity waves accentuates the gradient in a radial differential rotation rather than makes it uniform. This is similar to the tendency obtained in the case of momentum deposition by gravity waves due to radiative damping (Kim & MacGregor 2001;2003). The sharpening of the gradient of the radial shear due to the
negative viscosity could eventually lead to time variation in the tachocline (similarly to Kim & MacGregor 2001) or instability (e.g., see Petrovay 2003), causing a rapid radial mixing and thus reducing the anisotropy.

Even in the stably stratified radiative interiors of stars as well as in the tachocline, background turbulence has often been assumed to be present to enhance the value of effective viscosity. While the clarification of the source of turbulence responsible for such an enhanced eddy viscosity is an interesting problem, our results demonstrate how this residual turbulence interacts with gravity waves and shear flow, providing the prediction for the values of eddy viscosity as well as the particle diffusivity which depend on physical quantities like $A$ and $N$. In particular, the radial particle transport $D_{xx} \sim \xi_{\rho} \xi_{\mu}^{2/3} N^{-2}$ indicates that turbulent transport of particles can be inhibited due to stable stratification, shear flow and large radiative damping. This finding can have interesting implications for the surface depletion of lithium in the Sun and other stars (i.e., Pinsonneault 1997), and will be studied in a future publication. Furthermore, if a similar physical process operates in the bulk of the radiative interior of the sun, a negative viscosity that we obtain implies that a radial differential rotation which is created during its spin-down would not be eliminated. Note however that Charbonnel & Talon (2005) have shown an efficient momentum transport in the solar radiative interior due to the cumulative effect of large scale meridional flow, shear instability and gravity waves.

The tachocline is believed to possess a strong toroidal magnetic fields of strength $10^4 \sim 10^5$ G, which could have an important influence on turbulent transport in that region. This is an important problem since the presence of a weak poloidal magnetic field in the radiative interior together with a strong toroidal magnetic field in the tachocline (acting as a boundary layer between the radiative interior and convection zone) could offer a mechanism for a uniform rotation in the interior as well as for the tachocline confinement (e.g. Rüdiger & Kitchatinov 1996; MacGregor & Charbonneau 1997; Gough & McIntyre 1998) [see however Brun & Zahn (2006) for a negative result on this scenario]. In this case, the values of effective diffusivity of magnetic fields as well as eddy viscosity play a crucial role in determining the thickness of the tachocline. Therefore, a consistent computation of magnetic diffusivity and eddy viscosity with their dependences on physical quantities such as the strength of magnetic fields, the Brunt–Väisälä frequency, and shearing rate, would be of primary interest (Kim and Leprovost 2007). It is an interesting question, in general, whether a negative eddy viscosity, favored in a stably stratified medium, remains as a robust feature in the presence of magnetic field in view of the forward energy cascade (i.e. positive eddy viscosity) in MHD turbulence. Furthermore, composition gradients (discussed in Sec. 3) and meridional flows would contribute to the transport in the tachocline. In particular, meridional flows are expected to enhance the radial transport of chemical species by advection as discussed in Kim (2005) although this enhancement would be reduced for stronger horizontal turbulent [e.g., see Kim (2005) and Chaboyer and Zahn (1992)]. These issues are however outside the scope of this paper and will be addressed in future publication.
Here, again equation for $\hat{v}$ can be solved with the following solutions valid up to $O(\gamma^5)$:

$$\hat{v}_x = \hat{v}_y = \hat{v}_z = 0.$$
\[ \varpi(\tau) = \alpha - \frac{1}{8N} \frac{\gamma}{\gamma + \gamma^2}, \]
\[ \alpha = 1 - \frac{1}{8N}. \] (A.10)

By following a similar algebra used in Kim (2005) and by using the correlation function of the forcing given in Eq. (20), we can obtain the following correlation functions \( \langle v_i v_j \rangle \) leading orders in \( 1/N^2 \ll 1 \) and \( \xi_\mu \ll \mu^{-2}/\mathcal{A} \ll 1 \):

\[ \langle v_i^2 \rangle \sim \frac{\tau_f}{2A} \int \frac{d^3 k d\tau}{(2\pi)^3} \frac{\phi_{11}(k)}{\sqrt{\gamma + a^2} (\gamma + \gamma^2)^{1/2}} \left[ 1 + \cos \left[ 2(\varphi(\tau) - \varphi(a)) \right] \right]. \]
\[ \langle v_i v_j \rangle \sim -\frac{\tau_f}{2A N^2} \int \frac{d^3 k d\tau}{(2\pi)^3} \frac{\phi_{11}(k)}{\sqrt{\gamma + a^2} (\gamma + \gamma^2)^{1/2}} \left[ \frac{\tau^2}{\gamma} + e^{-2\xi_\mu Q(\tau,a)} \frac{\beta^2 \phi_{22}(k)}{\gamma^2} \right]. \]

Here, \( a = k_x/k_y \), \( Q(\tau,a) = (\gamma \tau + \gamma^3/3) - (\gamma a + \gamma^3/3) \); special symmetries \( \psi_{ij}(k_x) = \psi_{ij}(-k_x) \) and \( \psi_{ij}(k_c) = \psi_{ij}(-k_c) \) were used. We then compute \( \tau \) integrals in Eq. (A.11) in the strong shear limit \( \xi_\nu \ll \xi_\mu \ll 1 \) and use \( \langle v_i v_j \rangle = -\nu_t^2 \partial_t U_0 = \nu_t^2 \mathcal{A} \) to obtain Eqs. (26)-(28) and (31).

Next, to compute particle transport, we integrate Eq. (A.7) in time to obtain

\[ \hat{n}(k(t), t) = -\partial_\alpha n_0 \int dt_1 d^3 k_1 \hat{g}(k; k_1, t_1) e^{-D_Q(\alpha)} v_i(k_1, x, t_1). \] (A.12)

Here, \( Q(t, t_1) = \int_{t_1}^t dt'[k^2_1(t') + k^2_2] = [k^2_1 - k^2_1/3k_0\mathcal{A} + k^2_2(t - t_1)]; k^2_1 = k^2_2 + k^2_3 \) is the amplitude of wave number in the horizontal plane; \( k^2_1 = k^2_2 + k^2_3 \); \( \hat{g} \) is the Green’s function given by

\[ \hat{g}(k; k_1, t_1) = \delta(k_x - k_{1x}) \delta(k_y - k_{1y}) \delta(k_z - k_{1z}) \delta \left[ k_x - k_{1x} - k_{1y}(t - t_1)\mathcal{A} \right]. \] (A.13)

A similar analysis using Eqs. (A.9), (A.13), (14)-(15), and (20) and \( \langle nv_i \rangle = -D_{ij} \partial_j n_0 \) gives

\[ D^x_\tau = \int \frac{d^3 k d\tau}{(2\pi)^3} \xi_Q \phi_{11}(k) e^{-\xi_\mu Q(\tau,a)} \frac{\phi_{11}(k)}{\gamma^2} \left( \frac{\gamma + \gamma^2}{\gamma + a^2} \right)^{1/2}, \]
\[ D^y_\tau = \int \frac{d^3 k d\tau}{(2\pi)^3} \xi_Q \phi_{11}(k) e^{-\xi_\mu Q(\tau,a)} \frac{\phi_{11}(k)}{\gamma^2} \left( \frac{\gamma + \gamma^2}{\gamma + a^2} \right)^{1/2}. \] (A.14)

Here, \( \xi_\mathcal{D} = Dk^2/\mathcal{A} \sim \xi_\tau \ll 1 \). Finally, the evaluation of \( \tau \) integrals in Eq. (A.14) gives us Eqs. (29)-(30) in the main text.
