Abstract

Background: Yersinia pestis is the causative agent of plague. The two transcriptional regulators, PhoP and RovA, are required for the virulence of Y. pestis through the regulation of various virulence-associated loci. They are the global regulators controlling two distinct large complexes of cellular pathways.

Methodology/Principal Findings: Based on the LacZ fusion, primer extension, gel mobility shift, and DNase I footprinting assays, RovA is shown to recognize both of the two promoters of its gene in Y. pestis. The autoregulation of RovA appears to be a conserved mechanism shared by Y. pestis and its closely related progenitor, Y. pseudotuberculosis. In Y. pestis, the PhoP regulator responds to low magnesium signals and then negatively controls only one of the two promoters of rovA through PhoP-promoter DNA association.

Conclusions/Significance: RovA is a direct transcriptional activator for its own gene in Y. pestis, while PhoP recognizes the promoter region of rovA to repress its transcription. The direct regulatory association between PhoP and RovA bridges the PhoP and RovA regulons in Y. pestis.

Introduction

Yersinia pestis is one of the most dangerous bacterial pathogens. Humans infected with Y. pestis manifest three main forms: pneumonic, septicemic, and bubonic plagues, and it has a very high mortality rate without timely and effective antibiotic treatment [1]. There have been at least three plague pandemics in human history, including the Black Death, which accounted for the death of at least one-third of the European population between 1347 and 1353. Plague remains a great threat to public health because rodent plague epidemics are frequent in various natural plague foci, especially in Asia, America, and Africa, human plague infections are reported every year, and Y. pestis can possibly be used as a biowarfare or bioterrorism agent.

PhoP and PhoQ constitute a classic regulatory two-component system [2]. The sensor protein PhoQ responds to low environmental Mg\(^{2+}\), acidic pH, and host-secreted antimicrobial peptides, and then phosphorylates the response regulator PhoP. As a transcription factor, phosphorylated PhoP either activates or represses its target genes through binding to their promoter-proximal DNA regions. Intracellular growth of Y. pestis in macrophages occurs at early stages of systemic infection [3]. A phoP null mutant of Y. pestis showed reduced ability to survive in macrophages and human neutrophils, as well as under in vitro conditions of low pH, oxidative stress, high osmolarity, and antimicrobial peptides [4,5,6]; this mutant is slightly attenuated in mice [4]. As a global regulator, PhoP controls a very complex regulatory cascade in Y. pestis [7,8,9]. The PhoP regulons in Y. pestis and Salmonella enterica have considerable differences in terms of the functional changes in PhoP itself, as well as in the architecture of PhoP-dependent promoters. This allows the PhoP regulators to incorporate newly acquired genes into the ancestral regulatory circuits yet retain control of the core regulon members in these two bacteria [8,9]. The proven direct PhoP targets in Y. pestis include several genes that function in detoxification, protection against DNA damage, resistance to antimicrobial peptides, and adaptation to magnesium limitation [7], especially the mgtCB and udg loci that encode an Mg\(^{2+}\) transport system and a UDP-glucuronate decarboxylase for LPS modification, respectively, required for the replication of Y. pestis in macrophages [10]. These PhoP-dependent mechanisms used by Y. pestis contribute to intracellular growth of this pathogen.

As a member of the MarR/SlyA family of transcriptional regulators that control the virulence of multiple bacterial...
pathogens [11], RovA is required for the virulence of all three pathogenic yersiniae (Y. pestis, Y. pseudotuberculosis, and Y. enterocolitica) through regulation of various virulence loci [12,13,14,15,16]. In Y. pseudotuberculosis and Y. enterocolitica, RovA stimulates the transcription of inv, which encodes an invasin that mediates translocation across the intestinal epithelium [14,15,16,17]. However, the ins gene is naturally inactivated in Y. pestis due to the insertion of an IS200-like element within its coding region [18]. The rocA null mutant of Y. pestis is much more attenuated after subcutaneous inoculation than after intranasal or intraperitoneal route, indicating a more important role for RovA in Y. pestis [12]. In the intraperitoneal route, indicating a more important role for RovA [12]. The acquisition of this Y. pestis [12]. The pH6 antigen encoded by pstaABC acts as an antiphagocytic factor [19] and plays a more important role in bubonic plague than in the pneumonia and septicemic forms, closely mimicking the role for RovA [12]. The CUS-2 prophage is acquired by the Y. pestis ancestor and its genome forms an unstable episome in the pneumonia or systemic one [12]. In Y. pestis, RovA stimulates the transcription of the pstaEF, pstaABC, and CUS-2 prophage loci [12]. The pH6 antigen encoded by pstaABC acts as an antiphagocytic factor [19] and plays a more important role in pneumonia than in the pneumonia and septicemic forms, closely mimicking the role for RovA [12]. The pH6 antigen encoded by pstaABC acts as an antiphagocytic factor [19] and plays a more important role in bubonic plague than in the pneumonia and septicemic forms, closely mimicking the role for RovA [12]. The acquisition of this Y. pestis [12]. The acquisition of this Y. pestis [12].

The rocA gene transcribes with two distinct promoters, and the autoregulation of rocA has been established in Y. pseudotuberculosis, but whether both of the two promoters are dependent on RovA is unclear [17,23]. This study indicates that the autoregulatory mechanism is also conserved in Y. pestis, and further discloses that RovA stimulates both of the two promoters. In addition, PhoP responses to low magnesium signals, and recognizes the promoter region of rocA to repress its transcription in Y. pestis. The direct regulatory association between PhoP and RovA bridges the two distinct complexes of the bacterial membrane governed by the two regulators.

Materials and Methods

Bacterial strains

The wild-type (WT) Y. pestis biovar Microtus strain 201, avirulent to humans but highly virulent to mice, was isolated from Microtus brandti in Inner Mongolia, China, [24]. The base pairs 41 to 362 of rocA (432 bp in total length) or 41 to 631 of phoP (672 in total) were replaced with the kanamycin resistance cassette using the one-step inactivation method based on the lambda Red phage recombination system with the helper plasmid pKD46 [25]. This generated the rocA and phoP mutants of Y. pestis, designated as AtrocA and AphoP, respectively. Chromosomal integration of the mutagenic cassette was confirmed by PCR and sequencing using oligonucleotides external to the integrated cassette. The elimination of pKD46 in the mutants was verified by PCR. All primers used in this study are listed in Table 1.

A PCR-generated DNA fragment containing the rocA or phoP coding region with its promoter-proximal region (~300 bp upstream the coding sequence) and transcriptional terminator (~500 bp downstream) were cloned into the pACYC184 vector that harbors a chloramphenicol resistance gene (GenBank accession number X06405), as verified by DNA sequencing. The recombiant plasmid was subsequently introduced into AtrocA and AphoP, yielding the complemented mutant strains C-rocA and C-phoP, respectively.

Bacterial growth

The original chemically defined TMH medium [26] called “high magnesium, neutral pH” [I] and its different modifications were used for Y. pestis cultivation. The 20 mM MgCl₂ in the original TMH was changed to 10 μM to simulate the ‘low magnesium’ [II] condition. To simulate ‘mild acidic pH’ [III], the pH value of 7.2 in the original TMH was changed to 5.8. Overnight cell culture with an optical density (OD₆₀₀) of about 1.0 in each medium was diluted 1:20 into 18 ml of the corresponding fresh medium for further cultivation.

Cells were harvested at the middle-exponential or stationary phase for the followed primer extension or LacZ fusion assay. For cell harvest at the middle-exponential phase, bacteria were grown at 26°C with shaking at 230 rpm to enter the exponential phase; and then, half of the cell cultures were incubated at 37°C for 3 h and the remaining half were allowed to grow continuously at 26°C for 3 h. For harvest at the stationary phase, bacteria were grown at 26°C to enter the stationary phase; the cell cultures were then divided to grow at 37 and 26°C, respectively, for 3 h as above. The detailed time points for cell harvest were defined according to the bacterial growth

curves (Fig. 1). The above cultures grown at 37 and 26°C were designated as “shift from 26 to 37°C (#)” and “26°C continuously (&),” respectively, so as to determine the effect of temperature on gene transcription.

Primer extension assay

Total bacterial RNAs were extracted using the TRIzol Reagent (Invitrogen) [7,25]. Immediately before harvesting, bacterial cultures were mixed with RNXprotect Bacteria Reagent (Qiagen) to minimize RNA degradation. RNA quality was monitored by agarose gel electrophoresis and RNA quantity was determined by spectrophotometry. For the primer extension assay [7,25], an oligonucleotide primer complementary to a portion of the RNA transcript of rovA gene was employed to synthesize cDNAs from the RNA templates. About 10 μg of the total RNA from each strain was annealed with 1 pmol of [γ-32P] end-labeled reverse primer using a Primer Extension System (Promega) according to the manufacturer’s instructions. The same labeled primer was also used for sequencing with the fmol® DNA Cycle Sequencing System (Promega). The primer extension products and sequencing materials were concentrated and analyzed in a 6% polyacrylamide/8 M urea gel. The result was detected by autoradiography (Kodak film).

LacZ fusion and β-galactosidase assay

The 889 bp promoter-proximal DNA region of rovA was obtained by PCR with the ExTaq™ DNA polymerase (Takara) using Y. pestis 201 genome DNA as the template. PCR fragments were then directionally cloned into the EcoRI and BamHI sites of low-copy-number plasmid pRW50 that harbor a tetracycline resistance gene and a promoterless lacZ reporter gene [27]. Correct cloning was verified by DNA sequencing. An empty pRW50 plasmid was also introduced into each strain tested as the negative control. The Y. pestis strains transformed with the recombinant plasmids and the empty pRW50 plasmid were grown as previously described to measure the β-galactosidase activity in the cellular extracts using the β-Galactosidase Enzyme Assay System (Promega) [25]. Assays were performed with at least three biological replicates.

Purification of PhoP and RovA proteins

Preparation of the purified PhoP and RovA proteins were performed as previously described [7,25]. The entire coding region of the phoP and rovA genes of strain 201 was directionally cloned into the BamHI and HindIII sites of plasmid pET28a (Novagen). The recombinant plasmid encoding the 6× His-tagged PhoP and RovA proteins (His-PhoP and His-RovA, respectively)

Figure 1. Bacterial growth curves at 26°C. Overnight cell culture with an OD620 value of about 1.0 in each medium was diluted 1:20 into 18 ml of the corresponding fresh medium. Bacteria were then grown at 26°C with shaking at 230 rpm, and the OD620 values were monitored for each culture with a 3 or 4 h interval until the cultures reached the stationary growth phase (a, b, and c). Experiments were done with three biological replicates. Shown also is the design (d) for cell harvest for subsequent biochemical assays.

doi:10.1371/journal.pone.0025484.g001
were transformed into *Escherichia coli* BL21 λDE3 cells. Expression of His-PhoP or His-RovA was induced by the addition of 1 mM IPTG (isopropyl-β-D-thiogalactoside). The overproduced proteins were purified under native conditions using an Ni-NTA Agarose Column (Qiagen). The purified protein was concentrated with the Amicon Ultra-15 centrifugal filter device (Millipore) and the protein purity was verified by SDS-PAGE.

**Gel mobility shift assay (EMSA)**

The *rovA* promoter-proximal regions were amplified by PCR. For EMSA [7,25], the 3’ ends of DNA were labeled using [γ-^32^P] ATP and T4 polynucleotide kinase. DNA binding was performed in a 10 μl reaction volume containing binding buffer [1 mM MgCl₂, 0.5 mM EDTA, 0.5 mM DTT, 50 mM NaCl, 10 mM Tris- HCl (pH 7.5) and 0.05 mg/ml poly-(dl-dC)] labeled DNA (1000 to 2000 c.p.m/μl), and increasing amounts of the His-PhoP or His-RovA protein. Three controls were included in each EMSA experiment: 1) cold probe as specific DNA competitor (the same promoter-proximal DNA region unlabeled), 2) negative probe as nonspecific DNA competitor (the unlabeled coding region of the 16S rRNA gene), and 3) nonspecific protein competitor (rabbit anti-F1-protein polyclonal antibodies). After incubation at room temperature for 30 min, the products were loaded onto a native 4% (w/v) polyacrylamide gel and electrophoresed in 0.5× TBE buffer for about 50 min at 220 V. Radioactive species were detected by autoradiography after exposure to Kodak film at −70°C.

**DNase I footprinting**

For DNase I footprinting [7,25], the *rovA* promoter-proximal DNA regions with a single ^32^P-labeled end were PCR amplified with either the sense or antisense primer being end-labeled. The PCR products were purified using MinElute reaction cleanup columns (Qiagen). Increasing amounts of His-PhoP or His-RovA were incubated with the purified, labeled DNA fragment (2 to 5 pmol) for 30 min at room temperature, in a final 10 μl reaction volume containing the binding buffer used in EMSA. Before DNA digestion, 10 μl of Ca^2+/Mg^2+ solution (5 mM CaCl₂ and 10 mM MgCl₂) was added, followed by incubation for 1 min at room temperature. The optimized RQ1 RNase-Free DNase I (Promega) was then added to the reaction mixture, and the mixture was incubated at room temperature for 40 to 90 s. The reaction was quenched by adding 9 μl of stop solution (200 mM NaCl, 30 mM EDTA, and 1% SDS), followed by incubation for 1 min at room temperature. The partially digested DNA samples were extracted with phenol/chloroform, precipitated with ethanol, and analyzed in 6% polyacrylamide/8 M urea gel. Protected regions were identified by comparison with the sequence ladders. For sequencing, we used the fmo® DNA Cycle Sequencing System (Promega). The templates for sequencing were the same as the DNA fragments of DNase I footprinting assays. Radioactive species were detected as previously described.

**Results**

**Mutation and complementation**

Real-time RT-PCR experiments were performed to assess the relative mRNA levels of *phoP* and *rovA* in the corresponding WT, mutant, and complemented mutant strains. The *phoP* transcript was lacking in *ΔphoP*, but was restored in *C-phoP* relative to WT, and moreover similar results were observed for the *rovA* transcript in WT, *ΔrovA*, and *C-rovA* (data not shown). These data indicates the successful mutation and complementation of *phoP* and *rovA*.

To test whether the *phoP* or *rovA* mutation had the polar effect, the primer extension assays were conducted to detect the yield of the *rovA* primer extension product that represents the *rovA* transcriptional levels in the corresponding WT, mutant, and complemented mutant strains (Figure S1). As determined by several distinct methods (see below), the *rovA* gene was positively regulated by RovA under condition I, whereas it was under the negative control of PhoP under condition II. As determined by the primer extension assays herein, the *rovA* transcription under condition I was significantly repressed in *ΔrovA* relative to WT, and restored in *C-rovA*; its transcription under condition II was significantly elevated in *ΔphoP* relative to both *C-phoP* and WT (Figure S1). The *rovA* gene yielded almost the same transcriptional levels between the paired WT/*ΔphoP* or WT/*ΔrovA* strains. This complementation analysis confirmed that the observed PhoP or RovA-dependent transcription of *rovA* was due to the *phoP* or *rovA* mutation, respectively, rather than a polar mutation.

**Growth of WT, ΔrovA, and ΔphoP**

The growth curves of the WT, *ΔrovA*, and *ΔphoP* strains grown at 26°C under three different conditions I, II, and III were determined (Fig. 1). Under condition I, both *ΔrovA* and *ΔphoP* exhibited growth rates lower than WT (Fig. 1a). Under condition II, growth restriction was observed for *ΔphoP* rather than *ΔrovA* relative to WT (Fig. 1b). The three strains showed indistinguishable growth rates under condition III (Fig. 1c). For each strain, bacterial growth was impeded under suboptimal conditions II and III relative to the original condition I. In particular, bacterial cells exhibited very poor growth when each of strain was grown under condition II.

Bacterial cells were harvested at the middle-exponential or stationary phase for the following cell culture-related biochemical assays, and the time points for cell harvest were defined strictly according to the growth curves (Fig. 1d). It should be noted that bacterial cells grown under different conditions or those of different isogenic stains were harvested at the identical growth phase, rather than the identical optical density, which would deviate the secondary effects of growth rate or phase. In addition, temperature upshift from 26 to 37°C was designed prior to cell harvest, generating 26 (=26°C continuously) and 37°C (=shift from 26 to 37°C) grown cells.

**Transcription of rovA under different temperatures**

The primer extension experiments (Fig. 2) were then conducted to determine the yields of primer extension product of *rovA* (i.e., the relative *rovA* transcription levels, or the relative *rovA* promoter activities) in WT upon the above temperature upshift. The primer extension assay detected two transcriptional start sites located at 343 and 78 bp upstream of *rovA* (Fig. 2); therefore, two promoters (named P2 and P1, respectively) were transcribed for *rovA*. Under condition II, the P2 promoter activity showed no obvious change upon the temperature upshift. In condition I, the P2 promoter activity increased upon temperature upshift. Moreover, the P1 promoter activity decreased upon temperature upshift under all the three growth conditions. The stationary growth phase (Fig. 2b), the P2 promoter activity showed no obvious change upon the temperature upshift under conditions I, II, and III; yet, the P1 promoter activity decreased upon temperature upshift under all the three growth conditions. In conclusion, the temperature shift from 26 to 37°C triggered the down-regulation of both P2 and P1 promoters of *rovA* at the stationary growth phase. However, the down-regulatory effect occurred only for P2 at the middle-exponential growth phase.

For subsequent experiments, only bacterial cultures of “shift from 26 to 37°C” were analyzed, as 37°C is the temperature during human infections.

Figure 2. Transcription of rovA upon temperature shift from 26 to 37°C. Two oligonucleotide primers were designed to be complementary to the RNA transcript of rovA. The primer extension products were analyzed with 8 M urea–6% acrylamide sequencing gel. Lanes C, T, A, and G represent the Sanger sequencing reactions. Only the WT strain was tested to grow under conditions I, II and III, respectively. Bacterial cells were harvested at the middle-exponential (a) or stationary (b) phase. Temperature upshift was designed prior to cell harvest, generating two kinds of cultures: ‘26°C continuously’ (●) and ‘shift from 26 to 37°C’ (●). Detected were the two promoters P1 and P2 located at 78 (nucleotide T) and 343 (G) bp upstream of rovA, respectively. Images shown are representative of the results from at least three biological replicates.

doi:10.1371/journal.pone.0025484.g002

Autoregulation of RovA

A rovA-lac\_ fusion vector, containing the 889 bp promoter-proximal region of rovA and the promoterless lac\_ was transformed into both WT and ArovA to compare the rovA promoter activities in these two strains grown under conditions I, II, and III, respectively (Fig. 3a). Under all the three conditions, the expression of rovA significantly decreased in ArovA relative to WT. In addition, the primer extension experiments (Fig. 3b) were
conducted to compare the yields of primer extension product of rovA in WT and ΔrovA; the activities of both P1 and P2 promoters were under the positive control of RovA under all the three growth conditions, which was consistent with the above lacZ fusion data. Interestingly, the rovA transcription in WT were up-regulated under condition III relative to the other two conditions (Fig. 2a and 2b), and thus mild acid appeared to stimulate the rovA expression.

The 889 bp promoter-proximal region of rovA tested in the LacZ fusion assay was amplified, radioactively labeled, and subjected to EMSA with a purified His-RovA protein (Fig. 3c). The results show that His-RovA is able to bind to this DNA fragment in a dose-dependent manner in vitro (Fig. 3c). As further determined by DNase I footprinting (Fig. 3d), the purified His-RovA protected two distinct regions upstream of rovA against DNase I digestion in a dose-dependent manner. These two footprints, located from 592 to 502 bp (RovA site 2) and from 39 to 6 bp (Site 1) upstream of rovA, respectively, were considered RovA sites. Taken together, RovA is able to recognize all the promoters of its own gene to stimulate their activity in Y. pestis.

To test the affinity of RovA to Sites 1 and 2, EMSA was performed with two distinct rovA upstream DNA fragments containing Sites 1 and 2, respectively (Fig. 4). DNA retardation occurred at 0.74 pmol of His-RovA for the fragment containing Site 2 (Fig. 4a), whereas it was observed at 2.46 pmol for that containing Site 1 (Fig. 4b). This indicated that RovA had a much higher affinity to Site 2 than Site 1. The RovA proteins at all amounts used could not bind to the 16S rDNA fragment as the negative control, confirming the specificity of EMSA in this study (Fig. 4c).

Negative regulation of rovA by PhoP

The rovA-lacZ fusion vector (Fig. 3a) was transformed into both WT and ΔphoP to compare the rovA promoter activities in the two strains grown under conditions I, II, and III (Fig. 5a). Under conditions I and III, there was no significant difference in the rovA promoter activities in the WT and ΔphoP strains. Under condition

---

**Figure 3. RovA stimulated transcription of its own gene.** Only the bacterial cells of “shift from 26 to 37 °C” at the middle-exponential growth phase were analyzed herein. a) LacZ fusion. A promoter-proximal region 743 bp upstream to 146 bp downstream of rovA was cloned into pRW50 containing a promoterless lacZ reporter gene, and then transformed into WT or ΔrovA to determine the β-galactosidase activity in cellular extracts. Shown are the rovA promoter activities (Miller units) in ΔrovA or WT grown under conditions I, II and III, respectively. b) Primer extension. The P1 and P2 promoters of rovA were detected in ΔrovA or WT grown as described above. Lanes C, T, A, and G represent the Sanger sequencing reactions. c) EMSA. The radioactively labeled DNA fragment from the 743th bp upstream to the 146th bp downstream of rovA was incubated with increasing amounts of purified His-RovA protein, and then subjected to 4% (w/v) polyacrylamide gel electrophoresis. The band of free DNA disappeared with increasing amounts of His-RovA protein, and a retarded DNA band with decreased mobility turned up, which presumably represented the DNA-RovA complex. Shown on the lower side of the figure is the schematic representation of the EMSA design. d) DNase I footprinting. Labeled coding or non-coding DNA probes were incubated with increasing amounts of purified His-RovA (Lanes 1, 2, 3, and 4 containing 0, 4, 8, and 12 pmol, respectively), and subjected to DNase I footprinting assay. Lanes G, A, T, and C represent the Sanger sequencing reactions. The protected regions (vertical bars) are indicated on the right side of the image. The negative numbers indicate the nucleotide positions upstream of rovA. doi:10.1371/journal.pone.0025484.g003
II, the expression of rovA was significantly enhanced in the 

\( \text{DphoP} \) relative to the WT. Further primer extension experiments for rovA (Fig. 5b) again detected the two promoters, P1 and P2, when the bacterial cells were grown under the three conditions. P1 activity was under the negative control of PhoP under condition II, and independent of this regulator under the other two growth conditions. PhoP had no effect on P2 activity under all the three conditions. The EMSA assay disclosed that the purified His-PhoP protein was able to bind to the 889 promoter-proximal region of rovA in a dose-dependent manner in vitro (Fig. 5c). Subsequent DNase I footprinting experiments (Fig. 5d) indicated that His-PhoP protected a single region located from 102 to 47 bp upstream of rovA. This footprint was considered the PhoP site. Therefore, the rovA transcription is negatively controlled by the PhoP regulator under the low magnesium conditions through the PhoP-promoter DNA association.

**Promoter structure of rovA**

In this study, DNase I footprinting experiments precisely determined the PhoP and RovA sites for rovA. The primer extension assays mapped two promoters (P1 and P2) for rovA. Accordingly, the core promoter –10 and –35 elements for RNA polymerase recognition were predicted. Collection of data on the translation/transcription start sites, Shine-Dalgarno sequence (a ribosomal binding site in the mRNA), promoter –10 and –35 elements, as well as PhoP and RovA sites enabled us to depict the organization of PhoP and RovA-dependent promoters of rovA characterized herein (Fig. 6). The Y. pestis rovA promoter-proximal region is essentially identical to the Y. pseudotuberculosis one [28].

The two RovA sites within the rovA promoter-proximal region in Y. pestis are very similar to, although slightly different from, those determined in Y. pseudotuberculosis [17]. Y. pseudotuberculosis and Y. pestis have the same P2 promoter, but P1 in Y. pestis is 2 bp upstream of that in Y. pseudotuberculosis. The slight differences observed in the P1 sites and the RovA site sequences might be due to the personal inclination during DNA sequence reading.

**Discussion**

**Bacterial growth under magnesium-limitation conditions**

The magnesium cation (Mg\(^{2+}\)) is one of the essential elements for bacterial cell growth due to its function as a cofactor of enzymes. When grown under the condition II, Y. pestis cells exhibited poor growth, and moreover a extremely heavy restriction of growth was observed for DphoP. The Mg\(^{2+}\) transport systems are positively controlled by the Mg\(^{2+}\)-responsive PhoP regulator in Y. pestis [7,29], and the phoP mutation will impair the magnesium homeostasis of DphoP under Mg\(^{2+}\)-limiting environments [2].

**Regulation of rovA by growth temperature**

The three pathogenic yersiniae Y. pestis, Y. pseudotuberculosis, and Y. enterocolitica are ranked at different linkages in the evolution of the Yersinia genus [30]. The Y. pseudotuberculosis–Y. pestis clade diverged from Y. enterocolitica hundreds of millions of years ago, whereas Y. pestis from Y. pseudotuberculosis within thousands of years [31,32]. Consistently, Y. pseudotuberculosis and Y. pestis are very divergent from Y. enterocolitica, but share a very high level of genomic homology with each other.
As previously shown [17,33], two (P1 and P2) and three promoters are transcribed for rovA in Y. pseudotuberculosis and Y. enterocolitica, respectively, at room temperature (20 to 26 °C), but a down-regulation was observed at 37 °C. In addition to the mechanism of transcriptional regulation, the temperature control of rovA expression occurs also at the post-transcriptional level in Y. pseudotuberculosis [34]. In this study, P1 and P2 were also detected for rovA in Y. pestis. The temperature shift from 26 to 37 °C triggered the down-regulation of P1 promoter in Y. pestis at both stationary and middle-exponential growth phase. However, the down-regulation of P2 upon temperature upshift occurred only at the stationary phase rather than the middle-exponential one, indicating a growth phase-dependent effect for P2.

Regulation of rovA by transcriptional regulators

This study confirms that the autoregulation of rovA in Y. pestis is identical to that reported in Y. pseudotuberculosis, and further discloses that RovA stimulates the activity of both of the two promoters of its own gene in Y. pestis. The nucleoid-associated protein H-NS silences target genes by selectively targeting their upstream DNA sequences with GC contents lower than that of the resident genome [35]. Similarly, Y. pseudotuberculosis H-NS binds to a long DNA region upstream of P2 (Fig. 6), and represses the rovA transcription [17,23]. In addition, a LysR-type regulator RovM specifically binds to a short region closely upstream of the +35 element of P1 and far downstream of P2 (Fig. 6), and participates in the repression of rovA in Y. pseudotuberculosis [36]. Interestingly, the cooperation of RovM and H-NS is required for efficient silencing of rovA transcription [36]. It seems that the interaction of RovM and H-NS on the rovA promoter-proximal regions, which is accompanied by H-NS/RovM-DNA association, promotes the formation of a stable repressor complex to silence the rovA transcription [36].

The RovA Site 2 overlaps the H-NS site for rovA (Fig. 6), and RovA alleviates the H-NS-mediated repression of rovA by antagonizing the H-NS-promoter DNA association [17,23]. The RovA Site 2 is upstream of the −35 elements of both P1 and P2, and thus the transcriptional activation of P1 and P2 by RovA is a

Figure 5. PhoP repressed rovA transcription. Only the bacterial cells of “shift from 26 to 37 °C” at the middle-exponential growth phase were analyzed herein. a) LacZ fusion. The rovA-lacZ fusion vector as described in Fig. 3a was transformed into WT or ΔphoP to determine the rovA promoter activity (Miller units) when the bacteria were grown under conditions I, II and III, respectively. b) Primer extension. The P1 and P2 promoters of rovA were detected in ΔphoP or WT grown as described above. Lanes C, T, A, and G represent the Sanger sequencing reactions. c) EMSA. The labeled promoter-proximal fragment of rovA as described in Fig. 3c was incubated with increasing amounts of purified His-PhoP. Shown on the left side is the schematic representation of the EMSA design. Lanes C, T, A, and G represent the Sanger sequencing reactions. d) DNase I footprinting. The labeled DNA fragment from 228 bp upstream to 31 bp downstream of rovA was incubated with increasing amounts of His-PhoP. Lanes 1, 2, 3, 4 and 5 contained 0, 34.6, 41.5, 48.4 and 59.3 pmol, respectively. Vertical bars indicate the protected regions, whereas the negative numbers denote the nucleotide positions upstream of rovA. Lanes C, T, A, and G represent the Sanger sequencing reactions.

doi:10.1371/journal.pone.0025484.g005
H-NS [17,23] and RovM [36] sites are derived from those determined in essentially identical to the pH conditions. An 18-bp PhoP box sequence (TGTTTAW), which is consisted of a direct repeat of the heptanucleotide consensus (underlined), has been established previously [7]. This box consensus represents the conserved signals for PhoP recognition in Y. pestis [7]. PhoP binds to the phoP upsteam region [42]. The phoP transcription under low Mg²⁺ conditions [43,44], and PhoP footprints the slyA upstream region [45], which indicating that PhoP stimulates slyA directly through PhoP-promoter DNA association. H-NS binds to the phoP upstream region to silence the transcription of phoPQ operon under high Mg²⁺ conditions [45]. PhoP binds to the phoP upstream region and activates (i.e., autoregulates) the phoP transcription under low Mg²⁺ conditions [46,47]. SlyA also footprints with the phoP upstream region, and competes with H-NS since they share the same footprint that is adjacent to the PhoP site within the phoP upstream region [42]. Thus, the association between the phoP upstream region and SlyA will facilitate PhoP binding to the PhoP site by reducing the inhibitory activity of the H-NS protein [42]. Whether Y. pestis employs a regulatory feedback circuit involving in RovA and PhoP/PhoQ needs to be elucidated. In addition to RovA, PhoP, H-NS, and RovM sites are underlined with different lines. The H-NS [17,23] and RovM [36] sites are derived from those determined in Y. pseudotuberculosis, since the Y. pestis rovA promoter-proximal region is essentially identical to the Y. pseudotuberculosis one.

 doi:10.1371/journal.pone.0025484.g006

Figure 6. Organization of the rovA promoter-proximal region. The DNA sequence was derived from the genomic data of Y. pestis 91001 and the start codon was shown at the 3' terminal. The bent arrows indicate the two promoters P1 and P2 (transcription start sites). Predicted promoters −10 and −35 elements, and Shine-Dalgarno box are enclosed in boxes. The rovA, PhoP, H-NS, and RovM sites are underlined with different lines. The DNA sequence was derived from the genomic data of Y. pseudotuberculosis. Herein, a PhoP box-like sequence (TGTTTAW) is found in the PhoP site for Y. pseudotuberculosis upstream region [42]. The rovA transcription under magnesium-limiting conditions is activated by the PhoP/PhoQ system under low Mg²⁺ conditions [43,44], and PhoP footprints the slyA upstream region [45], which indicating that PhoP stimulates slyA directly through PhoP-promoter DNA association. H-NS binds to the phoP upstream region to silence the transcription of phoPQ operon under high Mg²⁺ conditions [45]. PhoP binds to the phoP upstream region and activates (i.e., autoregulates) the phoP transcription under low Mg²⁺ conditions [46,47]. SlyA also footprints with the phoP upstream region, and competes with H-NS since they share the same footprint that is adjacent to the PhoP site within the phoP upstream region [42]. Thus, the association between the phoP upstream region and SlyA will facilitate PhoP binding to the PhoP site by reducing the inhibitory activity of the H-NS protein [42]. Whether Y. pestis employs a regulatory feedback circuit involving in RovA and PhoP/PhoQ needs to be elucidated. In addition to Y. pestis and Y. pseudotuberculosis, the genus Yersinia still contains another pathogenic species, i.e., Y. enterocolitica, which shows a widely genetic diversity from the Y. pseudotuberculosis/Y. pestis clade. The DNA upstream of rovA in Y. enterocolitica differs greatly from the relevant Y. pseudotuberculosis/Y. pestis DNA. The Y. enterocolitica rovA gene is transcribed with the P1 and P2 promoters that are identical to

Class I stimulation dependent on the RNA polymerase α subunit C-terminal domain (αCTD) for function [23,37]. With the development of RovA autostimulation, the cellular RovA reaches a certain level; in this case, the low-affinity Site 1 is occupied by RovA. Notably, Site 1 is downstream of both P1 and P2, and accordingly the RovA Site 1 association blocks the entry of the RNA polymerase, which destroys the “endless” RovA-mediated activation of rovA transcription [23,37,38]. This RovA concentration-dependent regulation of its own gene allows the bacterium to finely modulate the cellular RovA levels for the most favorable production of RovA-dependent virulence factors [23,37,38].

As shown in this study, the PhoP regulator recognizes a single site within the rovA promoter-proximal region, and negatively controls the rovA transcription under magnesium-limiting conditions. It is further confirmed that PhoP as the responsive regulator of the PhoP/PhoQ two-component system responds to low magnesium conditions [7,8,9] rather than magnesium-rich or acidic pH conditions. An 18-bp PhoP box sequence (TGTTTAW-N₄TGTTTAW), which is consisted of a direct repeat of the heptanucleotide consensus (underlined), has been established previously in Y. pestis [7]. This box consensus represents the conserved signals for PhoP recognition in Y. pestis. Herein, a PhoP box-like sequence (TGTTTAW-N₄TGTTTAW) is found in the PhoP site for rovA. Notably, the promoter activity of P1, but not P2, is dependent on PhoP. The PhoP site overlaps the −10 region of the P1 promoter, and thus the PhoP-promoter association is thought to block RNA polymerase-DNA association, thereby repressing the transcription of rovA. This mode of regulator-promoter DNA interaction for transcriptional repression is frequently observed in transcriptional repressors, such as Fur [39] and Zur [40] in Y. pestis. PhoP and RovA control distinct complexes of cellular pathways, especially including those involved in virulence and host-adaptation [7,8,9,12,17,41]. The two regulons governed by PhoP and RovA, respectively, have evolved to merge into a single global regulatory circuit, due to the direct transcriptional association between PhoP and RovA.

The rovA upstream DNA sequences are identical in Y. pestis and Y. pseudotuberculosis, and moreover all the four regulators (RovA, PhoP, H-NS, and RovM) involved in the regulation of rovA are extremely conserved in these two bacteria. Therefore, the mechanisms that regulate rovA discussed above are conserved in these two bacteria.
those in \textit{Y. pseudotuberculosis}/\textit{Y. pestis}, and moreover a third promoter P3 downstream of P1 is detected. The differences in the promoters result in significantly lower levels of \textit{rovA} transcription in \textit{Y. enterocolitica}. H-NS binds to two regions upstream of \textit{rovA} to repress the \textit{rovA} transcription in \textit{Y. enterocolitica}. H-NS shows much lower affinities for either of the two sites than for the reported single \textit{Y. pseudotuberculosis}/\textit{Y. pestis} site. RovA stimulates the \textit{rovA} transcription in \textit{Y. enterocolitica} although the lack of observable RovA binding to the \textit{Y. enterocolitica} promoter. RovM binds to a single region upstream of \textit{rovA} to repress the \textit{rovA} transcription, as reported for \textit{Y. pseudotuberculosis}. Together, the cis-acting DNA region of \textit{rovA} has undergone great genetic variation between \textit{Y. enterocolitica} and \textit{Y. pseudotuberculosis}/\textit{Y. pestis}, which will lead to the remodeling in the mechanisms for controlling the \textit{rovA} transcription, although the relevant trans-acting factors (H-NS, RovA, and RovM) are highly conserved in the three pathogenic yersiniae.

Supporting Information

Figure S1 Primer extension assay for validation of nonpolar mutation. The \textit{rovA} or \textit{phop} null mutant (\textit{ArovA} or \textit{Aphop}, respectively) was generated from the wild-type strain 201 (WT), and then the corresponding complemented mutant strain (C-rovA or C-phop, respectively) was constructed. As determined by several distinct methods (see the text of manuscript), the PI promoter of \textit{rovA} was positively regulated by RovA when the bacteria were grown in the original TMH medium, but negatively controlled by PhoP when grown in the TMH containing 10\,\mu M MgCl\textsubscript{2}. Herein, an oligonucleotide primer, which was complementary to the RNA transcript of \textit{rovA}, was employed to detect the primer extension product that represented the relative PI promoter activity in the corresponding strains. The primer extension products were analyzed with 8 M urea–6\% acrylamide sequencing gel. Lanes C, T, A, and G represent the Sanger sequencing reactions. Shown on the right side of the image is the transcription start site (nucleotide T, corresponding to the PI promoter) that was located at 78 bp upstream of \textit{rovA}. The PI promoter was significantly repressed in \textit{ArovA} relative to both C-rovA and WT grown in the original TMH; yet, it was significantly enhanced in C-\textit{Aphop} relative to both C-\textit{Phop} and WT grown in the TMH containing 10\,\mu M MgCl\textsubscript{2}. The PI promoter was transcribed at almost the same level in every paired WT and complemented mutant. These results confirmed that the \textit{phop} or \textit{rovA} mutation was nonpolar.

Acknowledgments

The English writing of the manuscript was polished by EnPapers.
