Aims

To evaluate the anti-anginal and anti-ischaemic efficacy of the selective $I_f$ current inhibitor ivabradine in patients with chronic stable angina pectoris receiving beta-blocker therapy.

Methods and results

In this double-blinded trial, 889 patients with stable angina receiving atenolol 50 mg/day were randomized to receive ivabradine 5 mg b.i.d. for 2 months, increased to 7.5 mg b.i.d. for a further 2 months, or placebo. Patients underwent treadmill exercise tests at the trough of drug activity using the standard Bruce protocol for randomization and at 2 and 4 months. Total exercise duration at 4 months increased by 24.3 ± 65.3 s in the ivabradine group, compared with 7.7 ± 63.8 s with placebo ($P < 0.001$). Ivabradine was superior to placebo for all exercise test criteria at 4 months ($P$-values between < 0.001 and 0.018). Ivabradine in combination with atenolol was well tolerated. Only 1.1% of patients withdrew owing to sinus bradycardia in the ivabradine group.

Conclusion

The combination of ivabradine 7.5 mg b.i.d. and atenolol at the commonly used dosage in clinical practice in patients with chronic stable angina pectoris produced additional efficacy with no untoward effect on safety or tolerability.

Keywords

Ivabradine • Myocardial ischaemia • Stable angina pectoris • Heart rate • $I_f$ inhibition • Combination therapy

Introduction

Angina pectoris is typically caused by myocardial ischaemia owing to an imbalance between myocardial perfusion and oxygen demand. Elevated heart rate increases myocardial oxygen demand and limits tissue perfusion, the latter by reducing the duration of diastole during which most myocardial perfusion occurs. Long-term prognosis in patients with chronic stable angina pectoris is favourable1 and medical and interventional therapies show similar benefit.2,3 Thus, current treatment guidelines advocate an initial approach with medical therapy.4–6 Beta-blockers reduce myocardial ischaemia and prevent angina pectoris largely by lowering heart rate and are recommended as an initial therapy for stable angina pectoris, unless contraindicated.6–8

In modern clinical practice, however, many patients with stable angina pectoris require treatment with more than one anti-anginal drug, in addition to short-acting nitrates.6,9 Ivabradine is a pure heart rate-lowering agent that acts by inhibiting $I_f$, an important ionic current involved in the pacemaker activity in cells of the sino-atrial node.10 Ivabradine reduces the slope of spontaneous
diastolic depolarization in these cells and lowers heart rate at rest and during exercise. Given as monotherapy (with short-acting nitrates allowed as required), ivabradine has demonstrated anti-ischaemic and anti-anginal efficacy in randomized trials in patients with chronic stable angina pectoris when compared with placebo\(^{11}\) and has been shown to be non-inferior to atenolol\(^ {12}\) or amlopidine.\(^ {13}\) The drug has been recommended for the medical management of patients with stable angina pectoris who are intolerant of beta-blockers or in whom these agents are contraindicated.\(^ {6}\)

The primary purpose of the present study was to evaluate the anti-ischaemic and anti-anginal efficacy of ivabradine, relative to placebo, when given to patients with chronic stable angina pectoris receiving beta-blocker therapy.

**Methods**

**Study population**

Eligible patients were male and female outpatients aged \(\geq 18\) and \(< 75\) years, with a history of chronic angina pectoris on effort for \(\geq 3\) months before study entry, and evidence of coronary artery disease documented by one or more of the following criteria: myocardial infarction \(\geq 3\) months before study entry; percutaneous coronary angioplasty \(\geq 6\) months or coronary artery bypass surgery \(\geq 3\) months before study entry; coronary angiography showing \(\geq 50\)% diameter stenosis of one or more major coronary arteries; positive scintigraphic test showing exercise-induced reversible myocardial ischaemia; or a positive stress echocardiography showing regional wall motion abnormality and failure of normal rise in left ventricular ejection fraction with exercise. Other inclusion criteria included sinus rhythm at the pre-selection visit, current treatment with atenolol 50 mg o.d., or another beta-blocker at equivalent doses for at least 3 months. Patients had to show three positive symptom-limited exercise tolerance tests (ETTs) with the standard Bruce protocol during the run-in period and stability of ETT results between the second and third tests.

Exclusion criteria included: heart rate \(< 60\) b.p.m. on ECG at rest; significant heart disease other than coronary artery disease; angina pectoris at rest, unstable angina pectoris, Prinzmetal or microvascular angina; severe heart failure symptoms (New York Heart Association class III or IV); symptomatic hypotension or uncontrolled hypertension (resting systolic blood pressure \(> 180\) mmHg or diastolic blood pressure \(> 100\) mmHg); chronic or paroxysmal atrial fibrillation present at the pre-selection visit; atrial flutter; a pacemaker or implanted defibrillator; any condition that interferes with the ability to perform or interpret ETT (e.g. physical incapacity, Wolff–Parkinson–White syndrome, complete left bundle branch block, left ventricular hypertrophy); contraindication or intolerance to atenolol; previous treatment with atenolol at a dose \(> 50\) mg o.d., or another beta-blocker at a corresponding dose; recent treatment with amiodarone \(< 3\) months) or bepridil \(< 7\) days); known severe renal failure, liver function test abnormality, or known electrolyte disorder; anaemia (blood haemoglobin \(< 110\) g/L or 6.8 mmol/L); and thyroid disorders unless controlled by thyroxine for \(\geq 3\) months.

Written informed consent was obtained from all patients. The study was performed in accordance with the ethical principles stated in the Declaration of Helsinki, 1964, as revised in Washington, 2002. The study was approved by the institutional review board of each participating centre.

**Study design**

This was a randomized, double-blind, parallel-group study comparing the anti-anginal and anti-ischaemic effects of ivabradine with placebo when given to patients with chronic stable angina pectoris receiving the beta-blocker atenolol. The study consisted of a 6 to 8 week single-blind run-in period followed by a 4-month, double-blind treatment period (Figure 1). During the run-in period, all patients received atenolol 50 mg o.d. and placebo b.i.d. and underwent three ETTs. The first ETT took place 2 weeks after the pre-selection visit for patients already treated with atenolol 50 mg o.d., or 4 weeks after pre-selection for patients previously treated with another beta-blocker and switched to atenolol 50 mg o.d. on the day of pre-selection. The second ETT (2 weeks later) and the third ETT (10 days after the second ETT and designated as baseline, M0; Figure 1) were used to assess stability of patients’ ETT results. All three ETTs had to be positive (see details in what follows), and time to 1 mm ST-segment depression had to be within \(\pm 20\)% or \(\pm 1\) min between the second and third ETTs for patients to be included.

Included patients (i.e. those with positive and stable ETT results during the run-in period) were randomized to receive ivabradine or placebo given in combination with atenolol 50 mg o.d. for the entire double-blind treatment period. The ivabradine dose was 5 mg b.i.d. for 2 months, with a forced up-titration to 7.5 mg b.i.d. for the final 2 months, provided that resting heart rate was not \(< 50\) b.p.m. at the 2 month (M2) visit. The random allocation schedule was computer-generated using non-adaptive balanced randomization, stratified by the centre. An independent organization, Fisher Clinical Services, supervised randomization. Study treatment was allocated via an automated fax system. Ivabradine and placebo tablets were of similar appearance. Treatment efficacy was evaluated by further ETT at 2 and 4 months of study drug treatment (M2 and M4, respectively; Figure 1). Patients also kept an anginal symptoms diary, in which the occurrence of anginal attacks and the consumption of short-acting nitrates were recorded.

Short-acting nitrates could be taken as required, but not within 3 h before the ETT. Other drugs that could interfere with the natural course of angina pectoris (long-acting nitrates, calcium antagonists, other beta-blockers, potassium channel openers, molsidomine, trimetazidine) or the interpretation of ST-segment changes (anti-arrhythmic agents, digitalis, monoamine oxidase inhibitors) were not allowed during the trial. Drugs with known or suspected interactions with ivabradine (antifungal azole derivatives, macrolide antibiotics, cyclosporine, antiprotease agents) or atenolol (floctafenine, sulproide, clonidine, reserpine, guanethidine, melfloquine, anticholinesterase agents) were also not allowed.

The study was registered on the ClinicalTrials.gov website (identifier NCT00202566).

**Exercise tolerance testing**

Symptom-limited treadmill ETTs, using the standard Bruce protocol, were performed in the morning at approximately the same time of day on each visit. Patients did not take their morning dose of study treatment before ETT, so that tests were performed at the trough of drug activity for both the study drug and the background treatment, 12 h after the last intake of ivabradine and 24 h after the last intake of atenolol.

Time to onset of angina and time to limiting angina during ETT were determined by the investigator, whereas total exercise duration and time to 1 mm ST-segment depression were determined by central reading. Heart rate was obtained from the ECG recording, and rate–pressure product (heart rate \(\times\) systolic blood pressure) at rest...
and at peak exercise was determined using blood pressure measurements made by the investigator.

During the run-in period, ETTs were considered positive if stopped owing to the occurrence of limiting angina pectoris accompanied by at least 1 mm ST-segment depression between 3 and 12 min of exercise. During the treatment period (i.e. at M2 and M4), ETT could continue beyond 12 min or stop before 3 min, and stopping criteria included limiting angina pectoris, dyspnoea, and extreme fatigue. The ST-segment was measured 80 ms after the J-point in three consecutive QRS complexes with a flat baseline. If ST-segment depression was present at rest, the change was calculated from the value at rest to the value during exercise. If ST-segment elevation was present at rest, ST depression during exercise was calculated from the ECG isoelectric line. Thus, time to 1 mm ST-segment depression was calculated as the time to 1 mm ST-segment depression in the case of an isoelectric or elevated ST-segment at rest, and as the time to a further 1 mm depression in the case of ST depression at rest. During study drug treatment, if 1 mm ST-segment depression or angina did not occur during the ETT, total exercise duration was used as the measure of time to 1 mm ST-segment depression and time to onset of angina.

ETT and ECG tracings were analysed centrally at a reading centre by cardiologists blinded to treatment allocation. When reading the M2 and M4 ETT tracings during study drug treatment, the cardiologist did not have access to previous ETT data.

Endpoints
The primary efficacy endpoint was the change in total exercise duration from baseline (M0) to end of treatment (M4), measured during ETT at the trough of ivabradine activity in the full analysis set, defined as all randomized patients who took one or more doses of study medication and had one or more evaluations of the main efficacy endpoint. Secondary efficacy endpoints included changes from baseline to M4 in other ETT criteria, heart rate and rate–pressure product at rest and at peak of exercise, and changes from baseline to M2 in all ETTs, heart rate, and rate–pressure product criteria. Changes in anginal attack frequency and short-acting nitrate consumption recorded in patients' diaries were also analysed as secondary efficacy criteria.

Statistical analysis
The sample size was calculated to demonstrate the superiority of ivabradine compared with placebo in the primary efficacy endpoint. For a standard deviation of 110 s, 350 patients per group were necessary to detect a 30 s difference with 95% power and a one-sided type I error of 2.5%. Assuming withdrawal of 5% of patients after randomization, approximately 750 patients would have to be included in the study.

Data are presented as mean values ± SD, and 95% confidence intervals (two-sided) are given as appropriate. The main analysis of ETT criteria was performed on an intention-to-treat basis in the full analysis set, and the last non-missing value observed over a 4-month treatment period has been considered in the analyses. Groups were compared using a parametric covariance analysis adjusted for country factor and baseline value as covariate. The type I error was set at 2.5% (one-sided). Sensitivity analyses were also performed using a parametric analysis of variance without adjustment, and a non-parametric covariance analysis based on Wilcoxon rank norm with adjustment. For the frequency of anginal attacks and consumption of short-acting nitrates, 95% confidence intervals were calculated using a parametric analysis of variance without adjustment, and a non-parametric approach without adjustment based on the Hodges–Lehmann's estimator was used as sensitivity analysis. Safety analyses were performed on all patients who received one or more doses of study drug.
Results

Patient characteristics

In all, 889 patients from 219 centres in 20 countries were randomized to the ivabradine (n = 449) and placebo (n = 440) groups between August 2005 and June 2007. The full analysis set consisted of 875 patients (98% of those randomized), and the disposition of patients throughout the study including the run-in period is shown in Figure 2. A total of 26 patients withdrew early from study medications, 18 (4%) in the ivabradine group and 8 (2%) in the placebo group. In the ivabradine group, 393 patients (90%) had their dose up-titrated from 5 to 7.5 mg b.i.d. after 2 months of treatment.

The mean age of patients was approximately 60 years, 84% were male, 94% were Caucasian, and the majority (69%) was in Canadian Cardiovascular Society angina class II at baseline (Table 1). Clinical and ETT characteristics at baseline were similar between patients randomized to the ivabradine and placebo groups. Randomized patients showed good stability of ETT results between the second and third (M0) ETTs during the run-in period: mean total exercise duration differed by only \( \pm 24.3 \) s between the second (444 + 107 s) and third (448 + 106 s) run-in ETTs. All patients but three were in sinus rhythm at inclusion on centrally analysed ECG tracings.

Efficacy

The primary efficacy criterion, change in total exercise duration at M4 in the full analysis set, increased by 24.3 ± 65.3 s in the ivabradine group compared with 7.7 ± 63.8 s in the placebo group (\( P < 0.001 \)). More patients experienced an improvement in TED of >30 s in the ivabradine group (48%) than in the placebo group (34%, \( P < 0.001 \)). There were also improvements with ivabradine treatment, relative to placebo, in all other ETT criteria at M4 (\( P < 0.001 \) for all; Table 2, Figure 3).

Improvements in all ETT criteria, relative to placebo, were also seen in the ivabradine group at 2 months of therapy with ivabradine 5 mg b.i.d., (M2; Table 3) although the changes were larger at the end of the study and with higher doses.

Ivabradine treatment produced dose-dependent reductions in heart rate and rate–pressure product, both at rest and at the peak of exercise at M4 (Table 4). Corresponding reductions were also seen at M2, with further reduction at M4 in each case (Table 5). The frequency of angina attacks decreased significantly from baseline to M4 in both treatment groups, from 1.8 ± 3.3 to 0.9 ± 2.4 attacks/week in the ivabradine group, and from 1.6 ± 2.4 to 0.9 ± 2.1 attacks/week with placebo (between-group difference not significant). Among symptomatic patients [here defined as those who experienced one or more angina attacks during the run-in period, \( n = 625 \ (70\%) \)], angina attack frequency was reduced by 1.3 attacks/week (relative change –52%) with ivabradine and by 1.0

**Safety**

Ivasbradine was well tolerated in the study: the numbers of patients withdrawn from treatment owing to emergent adverse events were 13 (2.9%) in the ivasbradine group and 4 (0.9%) with placebo (difference not significant). Among these emergent adverse events, there were five serious in the ivasbradine group (1.1%) and three in the placebo group (0.7%). The most frequent causes of withdrawal related to bradycardia [ivasbradine five patients (1.1%), placebo none] and unstable or aggravated angina pectoris [ivasbradine three patients (0.7%), placebo one (0.2%)]. The most frequent emergent adverse events were those related...
to bradycardia, reported by 19 patients (4.2%) in the ivabradine group (12 patients with ivabradine 5 mg b.i.d. and 7 with ivabradine 7.5 mg b.i.d.) and 2 patients (0.5%) with placebo. Only 1.1% of adverse events related to bradycardia were symptomatic. Phosphenes (luminous phenomena described as increases in brightness in limited areas of the visual field) and blurred vision, which have been associated with ivabradine treatment in previous studies, were reported by nine patients (2%) in the ivabradine group and four (0.9%) in the placebo group. There were small, non-significant changes in supine blood pressure from baseline to the last value on treatment (from 127.3 ± 12.0 to 128.3 ± 14.8 mmHg for systolic blood pressure and from 78.6 ± 7.4 to 78.1 ± 8.0 mmHg for diastolic blood pressure with ivabradine, and from 127.6 ± 12.6 to 126.1 ± 14.8 and 78.1 ± 7.2 to 78.1 ± 7.5 mmHg, respectively, with placebo). There was one death during the treatment period, a fatal suicide in the ivabradine group and two deaths after the last study drug intake in the placebo group.

Discussion

The main finding from this study is that long-term heart rate reduction by ivabradine produced a significant improvement relative to placebo in the primary efficacy criterion, total exercise duration at the trough of drug activity at 4 months of treatment, in patients with chronic stable angina pectoris receiving the beta-blocker atenolol. There were also significant improvements with ivabradine in all ETT criteria at 2 months of treatment, with further improvement at 4 months after forced up-titration of the ivabradine dose from 5 to 7.5 mg b.i.d. These improvements in exercise capacity were accompanied by reductions in heart rate and rate–pressure product at rest and at the peak of exercise, which also were significant at 2 months and larger at 4 months.

The primary efficacy endpoint used in the present study, total exercise duration in standardized ETT at the trough of drug activity, is the one specified in current European guidelines. The dose of atenolol used as background therapy throughout the study was 50 mg per day. This reflects general clinical practice, and was the median atenolol dose in a recent population study of beta-blocker use in patients after an acute myocardial infarction. In spite of recommendation to titrate beta-blockers to full dosages, data in clinical practice reveal substantial underdosing of all beta-blockers, with dosages generally ≤50% than the dosages that randomized trials have proved to be effective. This could in part be related to reduced tolerability of higher doses of beta-blockers because of fatigue, depression, bronchospasm, or erectile dysfunction. Thus in patients who cannot be given higher doses of beta-blockers or in whom sufficient heart rate reduction cannot be achieved, the combination with ivabradine appears to be an appropriate therapeutic option.

Combination therapy is widely used in clinical practice in order to achieve adequate control of angina. In the Euro Heart Survey of the initial management of stable angina pectoris, the majority (59%) of patients were on two or more anti-anginal drugs. Among patients scheduled to be managed by medical therapy alone, the proportion was even higher at 80%. However, clinical trials evaluating combination therapy have yielded inconsistent results. Most studies have been small and many have not shown significant benefits of combinations as opposed to single-drug therapy. For example, the TIBET study, one of the largest studies of combination therapy, compared atenolol with slow-release nifedipine given alone and in combination, and showed no significant benefit of combination therapy for any...
ETT criterion. Similarly, studies of amlodipine or diltiazem on top of atenolol and the combination of amlodipine and atenolol showed no additional improvement in ETT criteria by adding a second drug to atenolol. A meta-analysis of randomized studies comparing the addition of a calcium antagonist to beta-blocker therapy and vice versa found small but significant benefits of combination therapy at the peak of activity of the added drug, but no significant improvements at the trough of activity. A recent positive trial of combination therapy involved the metabolic agent ranolazine given on top of atenolol (50 mg/day), amlodipine (5 mg/day), or diltiazem (180 mg/day) in patients with severe angina pectoris. The combination showed an improvement in total exercise duration, although changes in time to 1 mm ST-segment depression were not significant.

The present study, in terms of the size of the trial, the compliance with regulatory recommendations, and the consistency of significant improvements across all ETT criteria and time points, represents perhaps the most compelling single demonstration of the benefit of any combination of anti-anginal drugs published to date.

In the present study, treadmill ETTs were performed using the standard Bruce protocol, in which higher workloads are reached more rapidly than in the modified Bruce protocol. The more demanding standard Bruce protocol was chosen in view of the fact that patients were receiving background therapy known to improve exercise capacity. At baseline, resting heart rate was ~67 b.p.m. and mean angina attack frequency was only 1.6−1.8 attacks per week, compared with approximately 3.3 attacks per week in the published INITIATIVE study of ivabradine vs. atenolol in 939 patients with stable angina pectoris. In the current study, 264 patients (30%) recorded no angina attacks during the run-in period on background therapy alone. The low mean number of angina attacks at baseline may explain that we did not reach statistical significance for the reduction of angina attacks. The improvements in total exercise duration in the present study (on top of background beta-blockade) were numerically smaller than in the previous INITIATIVE study of ivabradine monotherapy that used the modified Bruce ETT protocol. Nevertheless, the additional 16.3 s in total exercise duration with ivabradine treatment in the present study, relative to placebo, was, on average, achieved at a walking speed of 5.5 km/h up a gradient of 14%. This represents a substantial additional workload in this context.

Ivabradine in combination with beta-blocker therapy was well tolerated in this study. Adverse events related to low heart rate are predictable with any heart rate-lowering therapy, and the

Ivabradine minus placebo, estimate from parametric approach adjusted on baseline and country factors.

Efficacy of ivabradine

low rate of withdrawal for this cause (1.1% in the ivabradine group) is notable, especially in the light of the low heart rate criterion (≥50 b.p.m.) for up-titration of the study drug. Visual symptoms, typically phosphenes, are thought to be related to the pharmacological action of ivabradine on ion channels in the retina that are similar to those responsible for the I f current in the sino-atrial node. Visual symptoms with ivabradine are typically mild and transient, without impact on daily activity of the patient. The incidence of adverse events related to visual symptoms with ivabradine (2.0% compared with 0.9% in the placebo group) was markedly lower than in previous studies.11,12 In these previous studies, patients were specifically asked about visual symptoms at study visits. In the present study, patients were informed of the possibility of visual symptoms before study commencement, but were not specifically asked about them during visits. Iivabradine directly and selectively inhibits the ionic channel in the sino-atrial node responsible for I f, a current that is important in pacemaker activity and the physiological regulation of heart rate.10,24,25 At therapeutic concentrations, ivabradine has no action at other cardiac ion channels or receptors and does not act via altering intracellular cyclic adenosine monophosphate levels. Consequently, ivabradine does not depress myocardial contractility6,27 or intracardiac conduction28 and has only minor effects on blood pressure as seen in this and previous studies.17 Thus, the unique haemodynamic profile of ivabradine can provide anti-ischaemic efficacy in addition to heart rate lowering with beta-blocker therapy, and this combination therefore represents a potential therapeutic strategy to treat patients with stable angina.

In conclusion, ivabradine treatment resulted in significant dose-dependent improvements in all ETT criteria relative to placebo in patients with stable angina pectoris receiving background therapy with atenolol. The starting dose of ivabradine was 5 mg b.i.d., which was increased at 2 months to 7.5 mg b.i.d. for a further 2 months. Improvements in all ETT criteria were significant at 2 months as well as at 4 months, indicating the efficacy of both ivabradine doses. The combination of ivabradine and atenolol was well tolerated, and the incidence of adverse events related to visual symptoms was markedly lower than reported in previous ivabradine studies. Thus, the combination of ivabradine 7.5 mg b.i.d. and atenolol at the commonly used dosage in clinical practice in patients with chronic stable angina pectoris produced additional efficacy with no untoward effect on safety or tolerability.
