Glass ionomer cement · Molar incisor hypomineralization · Dental caries · Posteruptive breakdown

Abstract
To evaluate the preventive effect of glass ionomer cement (GIC) against dental caries and posteruptive breakdown (PEB) on molars affected by molar incisor hypomineralization (MIH). In this randomized clinical trial, 77 children aged 5–9 years with at least 1 MIH-affected molar and without PEB or dentin caries lesions (\(n = 228\)) were included and randomly allocated to one of the following groups: (1) MIH-affected molars that remained unsealed and (2) MIH-affected molars that received GIC sealants. Dental caries and PEB were clinically evaluated after 6 and 12 months. Associations between dental caries and PEB with independent variables were evaluated using logistic regression analysis (\(p < 0.05\)). The MIH-affected molars allocated to the GIC sealant group were less likely to develop dental caries compared to those allocated to the unsealed group (OR = 0.23; 95\% CI 0.06–0.95). Conversely, application of a GIC sealant was not associated with prevention of PEB (\(p = 0.313\)). Furthermore, MIH-affected molars presenting yellow-brown opacities were almost 5 times more likely to develop dental caries (\(p = 0.013\)) and PEB (\(p = 0.001\)) compared to those presenting white-creamy opacities. We can conclude that GIC sealants can prevent dental caries on MIH-affected molars; however, the same protective effect was not observed for PEB.

Introduction

Molar incisor hypomineralization (MIH) is a qualitative dental enamel defect with different degrees of severity [Weerheijm et al., 2001]. This defect affects at least 1 out of 4 first permanent molars and is frequently associated with affected permanent incisors. The prevalence of MIH has been reported in several countries and the mean global prevalence is estimated to be between 13.1 [Schwender-dicke et al., 2018] and 14.2\% [Zhao et al., 2018], with no difference between males and females [Dave and Taylor, 2018]. In Mexico, the country where this investigation was carried out, a prevalence of 15.8\% has been reported among schoolchildren [Gurrusquieta et al., 2017].
MIH-affected teeth are characterized by demarcated opacities (white-creamy and yellow-brown) that may possess decreased hardness and increased roughness compared to normal enamel [Weerheijm et al., 2001; Weerheijm, 2003; Fagrell et al., 2010]. As a result, MIH molars may be more prone to enamel and dentin breakdown and to the development of atypical caries lesions [Farah et al., 2010]. Furthermore, patients with MIH often report hypersensitivity from affected teeth [Weerheijm et al., 2001]. This may hinder proper oral hygiene measures on surfaces that are already prone to plaque accumulation due to roughness. Combined, these factors are influential in the development of posteruptive breakdown (PEB) and rapid caries development [Weerheijm et al., 2001; Weerheijm, 2003; Fagrell et al., 2010], ultimately leading to an increased treatment burden [Grošelj and Jan, 2013; da Costa Silva et al., 2017].

The treatment modalities recommended for MIH-affected teeth vary widely depending on the severity of the defect and the presence of complicating factors, such as hypersensitivity, oral hygiene, and patient cooperation. The final treatment may also depend on the dentist’s training and the availability/accessibility of care. Therefore, strategies ranging from implementation of preventive measures to rehabilitation, and even extraction, can be indicated [Elhennawy and Schwendicke, 2016]. In mild cases, when neither PEB nor cavitated caries lesions are present, the application of pit and fissure sealants can be indicated. Pit and fissure sealants have been proven to be effective in preventing caries in non-MIH molars [Ahovuo-Saloranta et al., 2017]. Comparing different sealant materials, it has been shown that resin-based sealants present a higher longevity (retention rates) compared to glass ionomer cement (GIC) sealants [Kühnisch et al., 2012]; but no difference was reported regarding their caries-preventive effect [Beiruti et al., 2006]. In fact, Mickelnautsch and Yengopal [2016] showed that caries incidences between molars sealed with high-viscosity GIC or with resin-based sealants were similar.

When it comes to MIH-affected molars, little is known regarding the preventive effect of pit and fissure sealants, and contradictory results are found in the literature. While a retrospective study showed that fillings and sealants placed in MIH-affected molars had over 3 times greater probability of needing retreatment compared to the same interventions carried out on nonaffected molars [Kotsanos et al., 2005], another trial showed similar retention and secondary caries rates [Fragelli et al., 2017].

Although resin-based sealants are widely used in the prevention of caries in MIH/nonaffected molars [Fragelli et al., 2017; Cvikl et al., 2018], it must be acknowledged that resin-based sealants require optimal conditions for placement, including excellent moisture control [Naaman et al., 2017]. Conversely, GIC sealants are easier for the operator to apply and less vulnerable to moisture [Cvikl et al., 2018], and therefore they are a suitable alternative when resin-based sealants cannot be used due to moisture control issues. Indeed, GIC sealants are frequently used in MIH molars when sealing is indicated even before the tooth has completely emerged into the mouth and ideal moisture control is not possible [Kopperud et al., 2016]. However, to date, no research has investigated the preventive effect of GIC sealants applied on MIH-affected molars. Therefore, the aim of the present study was to evaluate the preventive effect of GIC sealants versus no sealant with regards to PEB and dental caries on MIH-affected molars after a 12-month follow-up period.

Materials and Methods

Study Design and Sample Size Calculation

This is a 2-arm, parallel-group, superiority trial that started in November 2018 and is planned to have a follow-up of 3 years. In this paper, we report the results after a 1-year follow-up. Participants were allocated to 1 of the 2 arms in order to compare the preventive effect of a GIC sealant (intervention group) versus no sealant (control group) on MIH-affected molars.

The sample size calculation was based on the primary outcome, i.e., the occurrence of PEB on MIH-affected molars of 29% after 1 year, as reported by Neves et al. [2019]. A minimum difference of 20% between the test and control groups was considered, and a power of 80% and a level of significance of 5% were adopted. Additionally, the sample size was increased to 40% to compensate for the design of this study (cluster per child), as more than 1 tooth could be included per child. Additionally, the final sample was increased to 20% to compensate for participant loss to follow-up. As a result, a minimum of 195 MIH-affected molars were required.

Eligibility Criteria

At baseline children were evaluated by 1 trained and calibrated pediatric dentist, with the same dentist performing the follow-up exams afterwards. The presence of MIH was evaluated according to the criteria proposed by Ghanim et al. [2017] and dental caries was evaluated according to International Caries Detection and Assessment System (ICDAS) criteria [Ismail et al., 2007]. The inclusion criteria were: children enrolled in elementary schools in Tepatlán de Morelos (Jalisco, Mexico), aged between 5 and 9 years, with cooperative behavior, presenting at least 1 MIH-affected molar with at least a two-thirds erupted crown. The exclusion criteria were: children with ongoing orthodontic treatment, presenting dental fluorosis, amelogenesis, or dentinogenesis imperfecta, and children with syndromes or developmental disorders. Additionally, MIH-affected molars presenting opacities not located on the occlusal surfaces of the tooth, with clinically visible dentin caries...
lesions and/or any PEB, restorations, or sealants, and MIH-affect-
ed molars with the occlusal surface totally or partially covered by a
gingival operculum, were excluded from this study.

The randomization unit was the child, so the included children
had between 1 and 4 MIH-affect ed molars included in the present
investigation. All of the included teeth from the same child were
allocated to either the sealant group or the no-sealant group. The
children were allocated to 1 of 2 groups using a randomization list
generated by a website (http://www.randomization.com) using blocks of different sizes (4, 6, and 8). Allocation concealment
was guaranteed by the use of opaque envelopes, which were opened
once the child was ready to receive an intervention.

Treatment Procedure
Sealants were applied by 2 final-year undergraduate dental stu-
dents from the Academic Centre for Dentistry Amsterdam (ACTA) under direct supervision of experienced pediatric den-
tists. Before the start of this study, the operators followed training
sessions, which comprised theoretical and practical laboratory-
ated examinations in extracted teeth, as well as in 15 patients not
participating in this study. Interexaminer agreement was calcu-
lected by comparing the scores given by the examiner and a "gold-
standard" examiner. After 1 week, the evaluator repeated the same
evaluations again for both MIH and dental caries outcomes in or-
der to determine the intra-agreement calculations. κ coefficient
values for MIH were 0.77 for interexaminer and 0.95 for intraex-
aminer reliability. For dental caries, κ values of 0.81 for interex-
aminer and 0.92 for intraexaminer reliability were achieved.

Evaluation and Clinical Follow-Up
Clinical evaluations were performed in school settings at base-
line and after 6 and 12 months. Clinical exams were performed
with the aid of a dental mirror, a periodontal probe, and an artifi-
cial light placed on the examiner’s forehead. Cotton wool rolls
were used for moisture control. Furthermore, a portable dental
unit (Robotin 1 HP; Remac Dent, Mexico City, Mexico) was used
to dry the teeth. Before each evaluation and sealant placement, the
dental surfaces were professionally cleaned using the same porta-
ble dental unit and a Robinson brush at a low speed. The only ex-
ception was the evaluation of the oral hygiene profile of the par-
ticipants, which was performed prior to teeth cleaning.

The primary outcome (PEB) was scored according to the crite-
ria proposed by Ghanim et al. [2017]. Each molar was given one of
the following scores: 0, no visible enamel defect; 1, enamel defect,
not MIH/HSPM; 2, demarcated opacities; 3, PEB; 4, atypical res-
toration; 5, atypical caries; 6, missing due to MIH/HSPM; or 7,
cannot be scored. A score of 7 was only used for teeth with exten-
sive coronal breakdown where the potential cause of breakdown
was impossible to determine. In cases where more than 1 score
could be given to the same tooth, the highest one was recorded. For
scores 2–6, the extension of the lesion was classified using the fol-
lowing scores: A, less than one third of the tooth is affected; B, at
least one third but less than two thirds of tooth are affected; and C,
at least two thirds of the tooth are affected. Demarcated opacities
were classified according to their color as white-creamy or yellow-
brown.

Dental caries was evaluated according to ICDAS criteria [Is-
mail et al., 2007] and given one of the following scores: 0, sound
surface; A, initial stage caries (first visual change in enamel); B, moderate stage caries (localized enamel breakdown or underlying
dark shadow); or C, extensive stage caries (visible cavitation in
dentin).

Sealant retention was evaluated according to the scoring system
proposed by Oba et al. [2009]. One of the following scores was
given: 0, fully retained sealant; 1, partially retained sealant, or 2,
absent sealant. The oral hygiene profile of the participants was as-
essed at the baseline evaluation using the Debris Index (DI) of the
Simplified Oral Hygiene Index (OHI-S) proposed by Greene and
Vermillion [1964]. Patient-related characteristics, such as age (in
years), sex (male or female), and distribution of the affected teeth
by jaw (upper/lower), were also collected.

Statistical Analysis
Data were tabulated and analyzed using Stata statistical soft-
ware (release 13; Stata Corp., College Station, TX, USA).

For the outcome PEB, a score of 2 indicated success and scores
3–6 indicated failure. For the outcome dental caries, scores A and
B indicated success while score C indicated failure. For the out-
come of sealant retention, scores 0 and 1 indicated success, while
a score of 2 indicated failure.

Clustered logistic regression analysis (children) was used to de-
termine the association between the outcomes PEB and dental car-
ies of MIH-affected molars with independent variables. First, a univariate logistic regression analysis was performed and all independent variables that reached a p value <0.20 were used in the adjusted analysis. Kaplan-Meier survival analysis and Cox regression analysis were used for the subgroup analysis (sealant group) to investigate the association between sealant retention and independent variables. A power analysis for this last subgroup analysis was performed. The statistical significance level was set at 5% for all analyses.

Results

A total of 77 children and 228 molars were included in this study (Fig. 1). The sample comprised 40 (51.95%) boys and 37 (48.05%) girls. At baseline, the mean age was 6.81 years (SD = 0.87, range 5–9 years). A total of 34 children had 4 MIH-affected molars were included in this research; 15 children had 3, 19 children had 2, and 9 children had only 1 MIH-affected molar included. Baseline characteristics such as sex, age, distribution of teeth by upper/lower jaw, color of opacities, extension of lesions, and oral hygiene at baseline were equally distributed between the sealant and no-sealant groups (Table 1). At baseline, a total of 14 teeth were not classified regarding the color of the opacity and 18 had missing data regarding the presence of (initial) dental caries. A total of 143 teeth had initial caries lesions at baseline (68.1% of the sample), with no differences between the groups.

After 12 months, 71 children and 213 molars were reassessed (dropout rate: 7.8%). From those, 113 molars

Analysis adjusted by age and gender. Values are presented as numbers (%) or means ± SD unless otherwise stated. a Statistically significant difference.
(53.1%) were in the no-sealant group and 100 (46.9%) were in the sealant group. Regarding the color of the opacity, 68.1% were white-creamy while 25.4% were yellow-brown.

The results of the clustered logistic regression analysis of the association between the presence of PEB and patient-related variables is displayed in Table 2. The results showed that the application of a GIC sealant did not protect molars against PEB, atypical restoration, atypical caries, or extraction due to MIH ($p = 0.313$). However, a significant association was observed regarding PEB and the color of the opacities, as teeth with yellow-brown opacities were 5 times more likely to have PEB, atypical restoration, atypical caries, or extraction due to MIH after a 1-year follow-up (OR = 5.80; 95% CI 1.01–32.83; $p = 0.041$).

The results of the clustered logistic regression for the association between dental caries and patient-related variables is depicted in Table 3 and demonstrated that sealed molars presented 77% less of a chance of caries progression compared to the no-sealant group (OR = 0.23; 95% CI 0.06–0.95; $p = 0.042$). Also, yellow-brown opacities were almost 5 times more likely to show signs of caries progression compared to white-creamy opacities (OR = 4.95; 95% CI 1.40–17.54; $p = 0.013$).

In relation to the subgroup analysis for sealant retention ($n = 100$), the survival rate of fully and partially retained GIC sealants was 91 and 83% after 6 and 12 months, respectively. Table 4 depicts the results of the Cox logistic regression for the subgroup analysis, in which no association between variables and sealant retention was found (power analysis = 78.2%). A χ² test for sealant group did not reveal any significant association between sealant retention and caries progression ($p = 0.663$) or PEB ($p = 0.746$).

**Discussion**

This is the first study to evaluate the preventive effect of GIC sealants applied in field conditions on the outcomes PEB and dental caries in MIH-affected molars. The results showed that molars that were not sealed were 77% more likely to develop dental caries compared to molars that received a GIC sealant application. This caries-preventive effect of GIC sealants has already been observed in previous investigations carried out on molars not affected by MIH [Yengopal et al., 2009; Mickenautsch and Yengopal, 2011; Cabral et al., 2018]. One of the factors that can explain this protective effect is that the material applied on occlusal surfaces acts as a mechanical bar-

Preventive Effect of GIC Sealants on MIH-Affected Molars

...carrier, physically isolating the pits and fissures from the oral environment [Muller-Bolla et al., 2006]. Additionally, one of the main advantages of GIC is fluoride release, which is associated with both caries prevention and arrestment [Bayrak et al., 2010; Mickenautsch et al., 2011]. In the case of MIH-affected molars, it has also been argued that sealant application helps to decrease hypersensitivity [Elhennawy and Schwendicke, 2016], enabling better plaque removal by the patient and therefore contributing to caries prevention.

This preventive effect was not observed for the outcome PEB, as no statistically significant difference was observed between MIH-affected molars that were sealed and those that remained unsealed \( (p = 0.313) \). It has been suggested that application of a GIC sealant can protect MIH-affected molars against PEB [Lygidakis, 2010] and the most accepted theory is that the fluoride present in this material may diffuse into the affected enamel and dentin, enhancing mineralization of the hypomineralized areas [Lygidakis, 2010]. A previous study proved this effect on enamel not affected by MIH [Kucukyilmaz and Savas, 2016]. We hypothesize that fluoride released from GIC can somehow improve the hardness of MIH-affected dental substrates; however, the results of our study suggest that this enhancement is not enough to prevent the occurrence of PEB.

In the present study, MIH-affected molars with yellow-brown colored opacities were more likely to develop dental caries and PEB than MIH-affected molars with white-creamy colored opacities. These results are in line with previous investigations [Da Costa-Silva et al., 2011; Neves et al., 2019] that reported more PEB after 12 months of evaluation on yellow-brown opacities. This is likely to be related to the fact that yellow-brown opacities are more porous and less mineralized than the white-creamy ones [Jälevik and Norén, 2000], which may be a risk factor for PEB [Da Costa-Silva et al., 2011].

This study suggests an association between the presence of dentin caries lesions and PEB. Although PEB had occurred in only 20 MIH-affected molars after 12 months, more than 50% of those molars (11 molars) showed dentine caries as well. MIH-affected molars are more prone to PEB as a result of a decreased phosphorus and calcium content in the enamel [Weerheijm et al., 2001; Weerheijm, 2003; Grošelj and Jan, 2013]; clinically, this can be translated to a more brittle enamel, which tends to break when submitted to masticatory forces [Weerheijm et al., 2001]. Once surface loss due to PEB has occurred, and the clinical stage of MIH has become more severe, plaque removal becomes difficult for the patient [Ebel et al., 2018]. However, it is not well established whether PEB leads to caries development or if dental caries is a contributing factor in the development of PEB.

---

**Table 4.** Subgroup analysis: association between sealant retention after 12 months and independent variables using a clustered Cox regression analysis

| Variable                                | Sealant survival, % | SE | Univariate HR (95% CI) | p value |
|-----------------------------------------|---------------------|----|------------------------|---------|
| Gender                                  |                     |    |                        |         |

| Total                                   | 83.00               | 0.03|                        |         |
factor to PEB. This area requires further exploration before a definitive conclusion can be drawn.

In this study, a cumulative survival rate of 83% for fully and partially retained sealants was determined after a period of 12 months, which is in line with previous studies using the same low-viscosity GIC when applied to molars not affected by MIH [Alsabek et al., 2019]. More importantly, this study found no association between sealant retention and dental caries or PEB. For dental caries, it has already been proven that sealant retention is not the most important parameter to be considered since, especially for GIC sealants, failures in retention cannot be considered a predictor for caries progression in permanent molars [Mickenautsch and Yengopal, 2013].

Along with its strengths, this study also has limitations. Blinding of the operators and the evaluator was not possible due to the nature of the interventions. Moreover, the short follow-up period could be considered a limitation. However, we plan to follow up these children for a period of 3 years. Another point of discussion is the detection of dental caries, as this study was carried out in field conditions, where the detection of initial- and moderate-stage caries lesions can be problematic. In order to overcome this possible drawback, only extensive caries (ICDAS/ICCMS score C) was considered as a failure for the outcome dental caries, mostly probably leading to underestimation of the disease. Therefore, we carried out the statistical analysis considering both moderate (ICDAS/ICCMS score B) and extensive lesions (ICDAS/ICCMS score C) as a failure, resulting in the same associations being found in the analysis. Nevertheless, most studies regarding the caries-preventive effect of GIC sealants have used the ICDAS/ICCMS score C as the caries cutoff point and, therefore it was deemed appropriate in terms of comparability to use the ICDAS/ICCMS score C as indicative of failure for the outcome dental caries in our trial. [Hilgert et al., 2015; de Amorim et al., 2018].

The choice of Fuji Triage (GC Europe) as the GIC for the sealants applied in this study was based on this material’s characteristics. Its low viscosity may increase the penetration of the material into the porosities of the hypomineralized enamel, and the pink color facilitates evaluation of the sealant during clinical exams. Additionally, this material can release 7–10 times more fluoride than the reinforced conventional GIC [Mast et al., 2013], possibly enhancing the preventive effect of this material when applied to MIH-affected enamel. These characteristics may result in this type of GIC being a suitable material for the sealing of MIH-affected molars, even when better results with the use of high-viscosity GIC in teeth not affected by MIH have been reported [Frencken et al., 2004]. Therefore, more research into these different types of GIC is required in order to guide the material choice in MIH-affected teeth.

The present study allows us to conclude that application of a GIC sealant on MIH-affected molars was effective in the prevention of dentin caries lesions after a follow-up period of 12 months. Conversely, this preventive effect was not observed for the prevention of PEB on those molars.

Acknowledgement

We would like to thank the schoolchildren, their parents, and the staff of the schools for their kind assistance in the conduction of this study. We are very grateful to Tina Mounessiani and Hiwa Mohajer Soltani for their dedication during the operative phase of this study. We would like to express our gratitude to GC Europe for kindly donating the materials used in this study and to Dr. Kirsten Fitzgerald and Charlotte McCarr for kindly reviewing the English language of this paper.

Statement of Ethics

This study followed the guidelines published by the Consolidated Standards of Reporting Trials [Schulz et al., 2010]. Ethical clearance to conduct this study was obtained from the Research Ethics Committee of the University of Guadalajara (protocol CUA/CEI/100/2018), and the study protocol is registered on ClinicalTrials.gov (NCT03870958). The children and their parents or legal guardians provided signed informed consent prior the start of this investigation.

Conflict of Interest Statement

The manufactures had no role in the study design, data collection and analysis, the decision to publish, or the preparation of this. The authors declare no conflict of interests.

Funding Sources

No funding sources contributed to this research.

Author Contributions

I.C.O., C.C.B., and D.H. conceived the ideas. M.S.S., A.P.R.G., and M.P. collected the data. I.C.O. and D.H. performed the statistical analysis and critical evaluation. All of the authors were involved in the writing of this paper and read and approved the final version of this work.
Preventive Effect of GIC Sealants on MIH-Affected Molars
