A phenomenological electronic stopping power model for molecular dynamics and Monte Carlo simulation of ion implantation into silicon

It is crucial to have a good phenomenological model of electronic stopping power for modeling the physics of ion implantation into crystalline silicon. In the spirit of the Brandt-Kitagawa effective charge theory, we develop a model for electronic stopping power for an ion, which can be factorized into (i) a globally averaged effective charge taking into account effects of close and distant collisions by target electrons with the ion, and (ii) a local charge density dependent electronic stopping power for a proton. This phenomenological model is implemented into both molecular dynamics and Monte Carlo simulations. There is only one free parameter in the model, namely, the one electron radius $r_e^2$ for unbound electrons. By fine tuning this parameter, it is shown that the model can work successfully for both boron and arsenic implants. We report that the results of the dopant profile simulation for both species are in excellent agreement with the experimental profiles measured by secondary-ion mass spectrometry (SIMS) over a wide range of energies and with different incident directions. We point out that the model has wide applicability, for it captures the correct physics of electronic stopping in ion implantation. This model also provides a good physically-based damping mechanism for molecular dynamics simulations in the electronic stopping power regime, as evidenced by the striking agreement of dopant profiles calculated in our molecular dynamics simulations with the SIMS data.

I. INTRODUCTION

Ion implantation in semiconductors is an important technology in integrated circuit device fabrication. A reliable description of as-implanted profiles and the resulting damage is needed for technological development, such as device design and modeling, as well as process optimization and control in the fabrication environment. For semiconductor devices whose physical dimensions are of order of submicrons or smaller, low implant energies and reduction of thermal processing are necessary, resulting in more prominent channeling effects in the as-implanted profiles and less post-implant diffusion. At these physical dimensions, it is essential to obtain the two- or three-dimensional details of the ever shallower and more compact dopant and damage profiles for post-implant diffusion simulations.

Study of the energy loss of channeled particles has a long history, for the channeling features can be used to elucidate the energy-loss mechanisms. Earlier analytical treatments of the implant profiles based on moment distributions, derived from the Lindhard-Scharff-Schiott theory (LSS), preclude channeling because of the amorphous nature of the targets assumed in the studies. Later, it was realized that, because of the channeling effect, electronic stopping power plays a much more significant role in ion implantation into crystalline solids than otherwise would be deduced from the application of the LSS theory to amorphous materials. It is especially true for heavy ion implants at low energies, such as arsenic ions in the energy range below 700keV. For implantation into silicon, most Monte Carlo (MC) models are only concerned with boron implants, and have not modeled arsenic implants accurately with an electronic stopping power model consistent with that used for boron. As will be shown below, the phenomenological model we developed for electronic stopping power can be factorized into (i) a globally averaged effective charge taking into account effects of close and distant collisions by target electrons with the ion, and (ii) a local charge density dependent electronic stopping power for a proton. This method is especially applicable at low energies, for which many-body, and multiple interactions are increasingly important. Although it is well known that the BCA is valid for high incident energies ($\sim 0.1$keV up to $\sim$MeV, the upper limit is set by relativistic effects), in a cascade, especially initiated by a relatively low energy ion, the energy of the ions will decrease and eventually reach the lower validity limit of the BCA at which many-body effects become important. For crystals of high symmetry, the BCA can be modified to account for simultaneous collisions in channel. Molecular dynamics (MD) results can provide good insight into how to successfully modify the BCA in this situation. Moreover, MD results can be compared to BCA Monte Carlo simulations and used to establish the low energy limits of the binary collision approximation.
An extremely important issue in deploying molecular dynamics to model collision processes in covalent and ionic solids is how to incorporate energy transfer mechanisms between electrons and ions. A good description of dynamical processes in energetic collisions, such as initial displacement damage, relaxation processes, and the cooling phase as the energy dissipates into the ambient medium, requires a theoretical framework that encompasses all interactions between ion-ion, ion-electron, and their interaction with the thermal surroundings. Especially, it should capture the nonequilibrium thermodynamic nature of these physical processes involving a wide range of energy scales, from a low energy electron-phonon interaction regime to a high energy radiation damage regime. Traditional MD simulations can capture the thermal behavior of an insulator. Since they do not take into account coupling between the phonons and the conduction electron system, obviously, these simulations underestimate the heat-transfer rate for noninsulating materials. In addition to lattice thermal conductivity, the issue of the conductivity due to electrons must be addressed. Furthermore, a correct description of the electronic stopping power should be incorporated into MD simulations for high energy implantation. For example, in sputtering processes by particle bombardment, examination of MD simulations with and without inelastic electronic energy loss has established that, independent of the ion’s mass or energy, the inelastic electronic energy losses by target atoms within the collision cascade have greater influence on the ejected atom yield than the ion’s electronic losses. This is in contrast to the belief that the electronic loss mechanism is important only for cascades initiated by light ions or by heavy ions at high bombarding energies. Although a convincing experimental verification of the electronic effects in sputtering is still lacking, the effects should be relevant to defect production rates, defect mobility and annealing, etc. Also as shown in Ref. 21, traditional MD simulations produce extremely long channeling tails due to the absence of electronic stopping. In order to incorporate the ion-electron interaction into molecular dynamics simulations, a simple scheme was proposed by adding a phenomenological term, which describes the inelastic electronic stopping in the high energy radiation damage regime, while also capturing the thermal conductivity by coupling low energy ions to a thermal reservoir. The empirical expression used in Ref. 22 for the strength of the ion-electron coupling is a function of the local electronic density. At the low charge density limit, a density functional result was reproduced, and at the high charge density limit, the linear response results were captured. In the same spirit, we develop a stochastic MD model incorporating the electronic stopping power as a damping mechanism. Our model is based on an effective charge theory with the electronic stopping power factorized into two parts. One is the effective charge of the incident ion, which is a globally averaged quantity determined by the average unbound electron density in the medium. The other factor is the electronic stopping power for a proton, for which the same local density functional results are used. Naturally, our damping mechanism incorporates both regimes, i.e., the electronic stopping regime and the electron-phonon interaction regime, into our molecular dynamics simulation, because the inelastic loss for a proton exhibits a similar density dependence as prescribed in Ref. 22 with additional modifications due to the velocity dependence of the effective charge. In the present work, however, we emphasize mainly the electron stopping power in the high energy regime (~keV to ~100keV), i.e., the electrons behave as an energy sink. The validity of the model for the electronic heat conduction regime will be discussed elsewhere. In the following, for boron and arsenic implants into single-crystal silicon in both the channeling and off-axis directions, we will show that a classical MD with the physically-based damping mechanism can generate dopant profiles in excellent agreement with experimentally-measured profiles obtained by secondary-ion mass spectrometry (SIMS).

As discussed above, the phenomenological model we have developed for electronic stopping power is successfully implemented into both BCA Monte Carlo programs and MD simulations. Wide applicability requires that a model be valid for different implant species over a wide range of energies. We emphasize that this electronic stopping model is accurate both for boron and arsenic implants, thus providing a crucial test of the generality and validity of the model in capturing the correct physics of electronic stopping.

The paper is organized as follows. In Sec. II, we present the phenomenological model for electronic stopping power in detail. Atomic units $\hbar = m_e = 1$ are used throughout the paper unless otherwise specified. In Sec. III, we briefly discuss different electronic stopping models implemented on the versatile BCA Monte Carlo simulation platform, MARLOWE. Then the results of the BCA Monte Carlo simulations on a rare-event algorithm enhanced UT-MARLOWE platform with our electronic stopping model are summarized. In Sec. IV, the results of the MD with the inelastic electronic energy loss are presented. In Sec. V, we make closing remarks and point out directions for future studies.

II. THE MODEL

According to the Brandt-Kitagawa (BK) theory, the electronic stopping power of an ion can be factorized into two components based on an effective charge scaling argument. One is the effective charge of the ion (if not fully ionized), $Z^*_i$, which is in general a function of ion velocity $v$ and the charge density of the target $\rho$, or equivalently,
the one electron radius \( r_s = [3/(4\pi \rho(X))]^{1/3} \); the other is the electronic stopping power for a proton, \( S_p(v, r_s) \). In the local density approximation, therefore, the total inelastic energy loss \( \Delta E_e \) of an ion of constant velocity \( v \) is

\[
\Delta E_e = \int [Z_1^*(v, r_s)]^2 S_p(v, r_s) dx,
\]

where the integral is along the ion path. Since the effective charge is a continuous function of electronic density, mathematically, it is always possible to find a mean value, \( r_s^* \) of \( r_s \), such that Eq. (1) can be rewritten as

\[
\Delta E_e = [Z_1^*(v, r_s^*)]^2 \int S_p(v, r_s) dx.
\]

If the effective charge is a slowly varying function of space, physically, this means that \( r_s^* \) describes an average number of unbound electrons in the sea and thus can be assumed to determine the Fermi surface. Therefore, we have the relation between the Fermi velocity and \( r_s^* \):

\[
v_F = \frac{1}{\alpha r_s^*},
\]

where \( \alpha = [4/(9\pi)]^{1/3} \). We note that this \( r_s^* \) will be the only tunable parameter in our electronic stopping power model.

Next we turn to a simple statistical model for this partially ionized, moving projectile. For an ion with \( N = Z_1 - Q \) bound electrons, where \( Q \) is the charge number of the ion of atomic number \( Z_1 \), a radially symmetric charge density

\[
\rho_e = \frac{N}{4\pi \Lambda^3} \exp \left( -\frac{r}{\Lambda} \right)
\]

is used in the BK theory. Here \( \Lambda \) is the ion size parameter, a function of the fractional ionization, \( q = (Z_1 - N)/Z_1 \). The total energy of the electrons comes from the sum of the kinetic energy estimated by the local density approximation, the electron-electron interaction in the Hartree approximation weighted by a variational parameter \( \lambda \) to account for correlation, and the Coulomb energy of the electrons in the electric field of the nucleus. A variational approach minimizing the total energy leads to the following dependence of the ion size on the ionization fraction \( q \):

\[
\Lambda = \frac{2a_0(1 - q)^{2/3}}{Z_1^{1/3} [1 - (1 - q)/7]},
\]

where \( a_0 = 0.24005 \). In the BK theory, the generalized Lindhard theory of the electronic stopping in a homogeneous electron gas with an electron density \( n = 3/(4\pi r_s^3) \) is used. The total electronic stopping is estimated from the sum of the energy loss in soft, distant collisions, i.e., small momentum transfers with target electrons seeing a charge \( qZ_1 \), and the energy loss to the target electrons experiencing increased nuclear interaction in hard, close collisions corresponding to large momentum transfers. As extensively discussed in the literature (see, e.g., Refs. 24, 26, 27, and references therein), it is assumed that the charge state of a proton in a solid is unity. Given an ionization fraction \( q \) and using the scaling argument for the ratio of ion stopping to the proton stopping at the same velocity, the BK theory produces a simple expression for the fractional effective charge of an ion:

\[
\gamma(\bar{r}_s) = q + C(\bar{r}_s)(1 - q) \ln \left[ 1 + \left( \frac{4\Lambda}{\bar{r}_s} \right)^2 \right],
\]

where \( C(\bar{r}_s) \) is weakly dependent on the target and has a numerical value of about 1/2. We will set \( C = 0.5 \) below. Then, the effective charge is

\[
Z_1^* = Z_1 \gamma(\bar{r}_s).
\]

For our model, using the procedure (2) outlined above, this dependence of \( \bar{r}_s \) is identified with the dependence of the mean value \( r_s^* \). Therefore, the effective charge \( Z_1^* \) has a nonlocal, i.e., spatially independent, character and depends on the Fermi surface. In the above discussion, as can be seen, \( q \) is a parameter which is not fixed by the BK theory. For obtaining this ionization fraction, there are velocity and energy criteria originally proposed by Bohr and Lamb, respectively. Kitagawa also used a statistical argument to justify scaling analyses in terms of the scaling parameter \( v_1/(v_B Z_1^{2/3}) \). Recently, the issue of which stripping criterion can give rise to a better physical understanding has been raised. However, in light of the large amount of experimental data employed in Ref. 27 to extract an ionization
scaling consistent with the Brandt-Kitagawa theory, we will use this empirically verified scaling in our model. As summarized in Ref. 27, a new criterion in the BK approach is proposed, i.e., a relative velocity criterion, which assumes that the electrons of the ion which have an orbital velocity lower than the relative velocity between the ion and the electrons in the medium are stripped off. The relative velocity \( v_r \) is obtained by averaging over the difference between the ion velocity \( v_1 \) and the electron velocity \( v_e \) under the assumption that the conduction electrons are a free electron gas in the ground state, therefore, whose velocity distribution is isotropic. Performing a further averaging of \( v_r \) over the Fermi sphere leads to

\[
v_r = v_1 \left( 1 + \frac{v_F^2}{5v_1^2} \right) \quad \text{for } v_1 \geq v_F, \tag{8}
\]

\[
v_r = \frac{3v_F^2}{4} \left( 1 + \frac{2v_F^2}{3v_F^2} - \frac{v_1^2}{15v_F^2} \right) \quad \text{for } v_1 < v_F. \tag{9}
\]

For the ionization scaling, a form of the Northcliffe type \(^3\) is then assumed for the scaling variable, i.e., the reduced relative velocity:

\[
y_r = \frac{v_r}{v_B Z_{1/3}}, \tag{10}
\]

where \( v_B \) is the Bohr velocity and \( v_B = 1 \) in our units. The extensive experimental data for ions \( 3 \leq Z_1 \leq 92 \) are used in Ref. 27 to determine

\[
q = 1 - \exp[-0.95(y_r - 0.07)]. \tag{11}
\]

In Ref. 27 an ionization scaling fit with even tighter bunching of the experimental data along the fit is presented. However, this approach entails a much more involved computational procedure. The accuracy level of Eq. (11) is adequate for our present purposes.

In our model, the electronic stopping power for a proton is derived from a nonlinear density-functional formalism. In the linear response theory, the energy loss per unit path length of a proton moving at velocity \( v \) in the electron gas is obtained by Ritchie

\[
\left( \frac{dE}{dx} \right)_R = \frac{2v}{3\pi} \left[ \ln \left( 1 + \frac{\pi}{\alpha r_s} \right) - \frac{1}{1 + \alpha r_s/\pi} \right], \tag{12}
\]

using an approximation to the full random-phase approximation dielectric function, which amounts to the exponential screening potential around the ion induced by density fluctuations of the electrons. The nonlinear, density-functional calculation based on the formalism of Hohenberg and Kohn, and Kohn and Sham \(^3\) has been performed to obtain the charge density and scattering phase shifts for the conduction band as a function of energy self-consistently. The final stopping power for a proton is obtained via

\[
\frac{dE}{dx} = \frac{3v}{k_F r_s} \sum_{l=0}^{\infty} (l + 1) \sin^2 \left[ \delta_l(E_F) - \delta_{l+1}(E_F) \right], \tag{13}
\]

where \( \delta_l(E_F) \) is the phase shift at the Fermi energy for scattering of an electron of angular momentum \( l \) and \( k_F \) is the Fermi momentum. As shown in Ref. 27, comparison with experimental data demonstrates that the density functional treatment provides an improvement over the linear response (dielectric) result, which underestimates the stopping powers. In our implementation, the result of the nonlinear, density functional formalism for the electronic stopping power for a proton is used, which can be expressed as

\[
S_p(v, r_s) = - \left( \frac{dE}{dx} \right)_R G(r_s), \tag{14}
\]

where, for computational convenience, the correction factor \( G(r_s) \) takes the form

\[
G(r_s) = 1.00 + 0.7177 r_s - 0.125 r_s^2 - 0.0124 r_s^3 + 0.00212 r_s^4 \tag{15}
\]

for \( r_s < 6 \). We note that a different correction factor was used in Refs. 12, which does not have the following desired behavior for \( r_s \ll 1 \). Since the density functional result converges to the Ritchie formula as \( r_s \) decreases
towards values sufficiently small compared to unity, this requires that the correction factor smoothly tend to unity as \( r_s \to 0 \). Obviously, the above \( G(r_s) \) possesses the correct convergence property.

The last ingredient needed for our model is the charge distribution \( \rho(\mathbf{x}) \) for silicon atoms in the crystal. We use the solid-state Hartree-Fock atomic charge distribution, which is spherically symmetric due to the muffin-tin construction. In this approximation, there is about one electron charge unit (0.798 electrons for Si) left outside the muffin-tin. This small amount of charge can be either distributed in the volume between the spherical atoms, resulting in an interstitial background charge density \( 0.119 \text{e/Å}^3 \), or distributed between the maximal collision distance used in Monte Carlo simulations and the muffin-tin radius (see details below).

### III. BCA MONTE CARLO SIMULATION RESULTS

First, in comparison with other electronic stopping models used in Monte Carlo simulations based on the MARLOWE platform, we stress that in our model the effective charge is a nonlocal quantity, neither explicitly dependent on the impact parameter nor on the charge distribution, and the stopping power for a proton depends on the local charge density of the solid. A purely nonlocal version of the BK theory was implemented into MARLOWE, in which both the effective charge and the stopping power for a proton depend on a single nonlocal parameter, namely, the averaged one electron radius. Its results demonstrated that energy loss for well-channeled ions in the keV region has high sensitivity to the one-electron radius in the channel. It was pointed out that a correct density distribution is needed to account for the electronic stopping in the channel. Later, a purely local version of the BK theory was developed to take into account the charge distribution of the electrons. Comparison with other electronic stopping models, such as Lindhard and Scharff-Firsov, and the above nonlocal implementations showed a marked improvement in modeling electronic stopping in the channel. Good agreement between simulated dopant profiles and the SIMS profiles for boron implants into (100) single crystal silicon was obtained. However, this purely local implementation of the BK theory did not successfully model the electronic stopping for the boron implants into the (110) axial channel and arsenic implants is noted in Ref. 2.

In the present work, UT-MARLOWE was selected as the platform for our electronic stopping model implementation. UT-MARLOWE is an extension of the MARLOWE code for simulating the behavior of energetic ions in crystalline materials. It has been enhanced with: (i) atomic pair-specific interatomic potentials for B-Si, B-O, As-Si, As-O for nuclear stopping, (ii) variance reduction algorithm implemented for rare events, (iii) important implant parameters accounted for, e.g., tilt and rotation angles, the thickness of the native oxide layers, beam divergence, and wafer temperature, etc. In our simulations, we have turned off certain options, such as the cumulative damage model in the UT-MARLOWE code, which is a phenomenological model to estimate defect production and recombination rates. Individual ion trajectories were simulated under the BCA and the overlapping of the damage caused by different individual cascades was neglected. In order to test the electronic stopping model we also used low dose (\( 10^{13} \text{cm}^{-2} \)) implants so that cumulative damage effects do not significantly complicate dopant profiles. Also, for the simulation results we report below, 16Å native oxide surface layer, 300K wafer temperature were used. The maximum distance for searching a collision partner is 0.35 lattice constant, the default value in the UT-MARLOWE. The excess charge outside the muffin-tins is distributed in the space between this maximum collision distance and the muffin-tin radius. In the simulation, the electronic stopping power is evaluated continuously along the path the ion traverses through regions of varying charge density, i.e., the energy loss is given by

\[
\Delta E_e = \int_{\text{ion path}} \left[ Z_1 \cdot \gamma(v_1, r_s^{p}) \right]^2 S_p(v_1, r_s(x)) \, dx. \tag{16}
\]

In the simulations, the free parameter \( r_s^{p} \) was adjusted to yield the best results in overall comparison with the experimental data. The value \( r_s^{p} = 1.109 \text{Å} \) was used for both boron and arsenic ions for all energies and incident directions. This value is physically reasonable for silicon. Note that the unbound electronic density in silicon with only valence electrons taken into account will give rise to a value of 1.061Å for \( r_s \). The fact that our \( r_s^{p} \) value is greater than 1.061Å indicates that not all valence electrons participate in stopping the ion as unbound electrons. We display the Monte Carlo dopant profile simulation results as follows. We note in passing that the lower and upper limits of energy used in our simulations are determined by the energy range of the SIMS data available to us. In Figs. 1, 2, and 3, we show boron dopant profiles for the energies 15keV, 35keV, and 80 keV along (100), (110), and the off-axis direction with tilt = 7° and rotation = 30°, respectively. It can be seen that the overall agreement with the SIMS data is excellent. In Fig. 1, the simulations show a good fit for the cutoff range. In the high energy regime, the simulated distribution shows a slightly peaked structure. This can be attributed to a strong channeling due to insufficient scatterings in the implants. We have noticed that by increasing, e.g., the native oxide layer thickness, the peak can be reduced. For the (110) channeling case, the distribution indicates a possibility that the total electronic
stopping power along the channel is a little too strong at the high energy end. However, it should be kept in mind that for this channel, the UT-MARLOWE model becomes sensitive to the multiple collision parameter which is employed as an approximate numerical correction for the effect of multiple overlapping nuclear encounters. It is not clear how to separate the contributions from these two different sources.

For comparison, in Fig. 4 we also display a low energy (5keV) implant case. Again the agreement for both the channeling and off-axis directions is striking (thin lines without symbols). In order to illustrate the importance of electronic stopping power at this low energy for boron implants, we have used an artificially reduced electronic stopping power, i.e., multiplying $\Delta E_e$ in Eq. (14) by a factor of 1/10 in the simulation, to generate dopant profiles in the channeling and off-axis directions. From Fig. 5, it is evident that, for boron implants even in this low energy regime, electronic stopping power has significant influence on the channeled tail of the dopant distribution and on the cutoff range for both channeling and off-axis directions.

Figs. 5 and 6 show arsenic dopant profiles for energies ranging from 15keV to 180keV along $\langle 100 \rangle$, and the off-axis direction with tilt = 8° and rotation = 30°, respectively. It can readily be concluded that our electronic model works successfully with arsenic as well as boron implants into crystalline silicon. For comparison, a case of arsenic implant into amorphous silicon is also shown in Fig. 7. The implant energy is 180keV. The effect of electronic stopping, which shows clearly in the long sloping channeling tail in the crystalline counterpart (see Fig. 5), is less prominent for the amorphous case (Fig. 7).

To examine the role that electronic stopping power has on arsenic implants in the low energy regime ($\sim 5keV$), we again simulated arsenic dopant profiles with the artificially reduced electronic stopping power. For these low energy implants, the oxide layer thickness 3Å were used in the BCA simulations on account of the fact that the wafers used for these implants were treated by dilute HF etch for 30 seconds, then implanted within 2 hours to prevent native oxide regrowth. In Fig. 6, we show that our electronic stopping power model is successful in both the $\langle 100 \rangle$ channeling and off-axis directions (thin lines without symbols). Clearly, the artificial reduction of electronic stopping power leads to incorrect dopant distributions and cutoff ranges for both the channeling and off-axis directions, although the deviations indicate a less significant contribution from electronic stopping for arsenic implants than for boron implants at the energy 5keV. However, the deviation in the cutoff range due to the electronic stopping power reduction for the channeling case is still significant. Obviously, this reinforces the conclusion that, for channeling implants even at low energies, electronic stopping is not negligible.

In summary, the above results demonstrate clearly that our electronic stopping power indeed captures the correct physics of the electronic stopping for ion implants into silicon over a wide range of implant energies.

IV. MD SIMULATION RESULTS

We have also used classical molecular dynamics simulation to study the electronic stopping power as one of the damping mechanisms in the high energy regime, as discussed above. Here we demonstrate that experimental data, such as SIMS, can be used to test the validity of this physically-based damping model. The interaction between silicon atoms are modeled by Tersoff’s empirical potential:

$$ E = \frac{1}{2} \sum_{i\neq j} f(r_{ij}) \left[ V_R(r_{ij}) - b_{ij} V_A(r_{ij}) \right], $$

where $f(r_{ij})$ is a cutoff function that restricts interactions to nearest neighbors, $V_R(r_{ij})$ and $V_A(r_{ij})$ are pair terms, and $b_{ij}$ is a many-body function that can be regarded as an effective Pauling bond order. We have modified the repulsive part of the Tersoff potential by splicing to the ZBL universal potential at close-range. The ZBL universal potential is also used to model the ion-silicon interactions. In our full MD simulations for the low dose implantation, the lattice temperature was initialized to 300K and the above electronic stopping model was applied to all the atoms. The only modification required for implementation in MD is to take into account the contributions from multiple silicon atoms to the local electron density, while ensuring that the background electron density is only counted once. For each individual cascade, all recoils and the accumulation of damage in the ion path are taken into account. Using the parameter value 1.109 for $r_0^s$ from the comparison of BCA Monte Carlo simulation results with the SIMS data, we have simulated the implantation of low energy boron and arsenic ions into the Si $\{100\}(2 \times 1)$ surface at energies between 0.5keV and 5keV, with both channeling and off-axis directions of incidence. We mention here that, for the $\langle 100 \rangle$ channeling case up to 0.16 keV (32%) of 0.5 keV boron implant energy and 0.64 keV (13%) of 5keV arsenic implant energy are lost via electronic stopping in our simulations. Simulations were terminated when the total energy of the ion became less than 5eV, giving typical simulation times of around 0.2ps. Figs. 8, 9 and 10 show the calculated dopant concentration profile for various energies and directions. Each MD profile is generated by a set of between 500 and 1300 individual ion trajectories. Also shown are the profiles obtained using the modified
UT-MARLOWE BCA code described in Sec. III. Obviously, the MD calculation results are in very good agreement with the experimental data, and with the BCA results. This demonstrates that our electronic stopping power model provides a good physically-based damping mechanism for MD simulations of ion implantation.

V. CONCLUSION

We have developed a phenomenological electronic stopping power model for the physics of ion implantation. It has been implemented into MD and BCA Monte Carlo simulations. SIMS data have been used to verify this model in the MD and BCA Monte Carlo platforms. This model has only one free parameter, namely, the one electron radius of unbound electrons in the medium. We have fine tuned this parameter to obtain excellent results of dopant profiles compared with SIMS data in both MD and BCA Monte Carlo simulations. We emphasize that this model with a single parameter can equally successfully model both boron and arsenic implants into silicon over a wide range of energies and in different channeling and off-axis directions of incidence. This versatility indicates wide applicability of the model in studies of other physical processes involving electronic stopping. As a more stringent test of the model, it should also be applied to implantation of species other than boron and arsenic. Using arsenic implantation as an example, we have also addressed the issue of how significant electronic stopping is for heavy ions in a low energy regime. For instance, to achieve a good quantitative understanding, we still have to take into account the physics of electronic stopping for arsenic implants at 5keV.

As discussed above, it is important to incorporate ion-electron couplings into MD simulations in both the high energy radiation damage regime and the low energy electron-phonon interaction regime. We have demonstrated that this model provides a crucial piece of physics in MD simulations for modeling energetic collisions in the electronic stopping power regime. The agreement of the simulated dopant profiles with the SIMS data shows that the incorporation of this physically-based damping term into MD simulations is a phenomenologically reliable approach in the regime concerned. Under way is an investigation of whether it can be used as a good phenomenological model for electron-phonon coupling in the low energy regime. This agreement also suggests that MD can be used to generate dopant profiles for testing against the low energy BCA results when experimental data is not available. Furthermore, MD simulations incorporating this physically-based damping mechanism can provide valuable insight into how to modify the binary collision approximation. This will enable the validity of the Monte Carlo simulation to be extended further into the lower energy regime, while not destroying computational efficiency required in realistic simulation environments.

VI. ACKNOWLEDGMENT

We thank Al Tasch for useful discussions and for providing us with SIMS data, which facilitate validation of the model. This work is performed under the auspices of the U.S. Department of Energy.

VII. FIGURES

FIG. 1. Boron implant profiles for the ⟨100⟩ direction with energies ranging from 15keV to 80keV. Zero tilt and rotation angles. The thick lines are SIMS data.

FIG. 2. Boron implant profiles for the ⟨110⟩ direction with energies ranging from 15keV to 80keV. Zero tilt and rotation angles. The thick lines are SIMS data.

FIG. 3. Boron implant profiles for the ⟨100⟩ direction with the tilt = 7° and rotation = 30°. The thick lines are SIMS data.
FIG. 4. Boron implant profiles for the $\langle 100 \rangle$ channeling and for the off-axis direction with the tilt $= 7^\circ$ and rotation $= 7^\circ$. The implant energy is 5keV. Thick lines: SIMS data; Thin lines without symbols: BCA Monte Carlo simulation with full electronic stopping power; Circles: BCA Monte Carlo simulation with the artificially reduced electronic stopping power for the channeling case; Triangles: the corresponding case for the off-axis direction (see text).

FIG. 5. Arsenic implant profiles for the $\langle 100 \rangle$ direction with energies ranging from 15keV to 180keV. Zero tilt and rotation angles. The thick lines are SIMS data.

FIG. 6. Arsenic implant profiles for the $\langle 100 \rangle$ direction with the tilt $= 8^\circ$ and rotation $= 30^\circ$. The thick lines are SIMS data.
FIG. 7. Arsenic implant profile into amorphous silicon with the implant energy being 180keV. The thick line is SIMS data.

FIG. 8. Arsenic implant profiles for the ⟨100⟩ channeling and for the off-axis direction with the tilt = 10° and rotation = 22°. The implant energy is 5keV. Thick lines: SIMS data; Thin lines without symbols: BCA Monte Carlo simulation with full electronic stopping power; Circles: BCA Monte Carlo simulation with the artificially reduced electronic stopping power for the channeling case; Triangles: the corresponding case for the off-axis direction (see text).

FIG. 9. Molecular dynamics simulation: boron implant profiles into the ⟨100⟩ channel with tilt = 10°, rotation = 22°. Implant energy is 5keV. Thick line: SIMS data. Thin line: MD simulation. Dotted line: BCA Monte Carlo simulation.
FIG. 10. Molecular dynamics simulation: arsenic implant profiles into the ⟨100⟩ channel with zero tilt, rotation angles. Implant energy is 5keV. Thick line: SIMS data. Thin line: MD simulation. Dotted line: BCA Monte Carlo simulation.

FIG. 11. Molecular dynamics simulation: arsenic implant profiles into the ⟨100⟩ channel with tilt = 10°, rotation = 22°. Implant energy is 5keV. Thick line: SIMS data. Thin line: MD simulation. Dotted line: BCA Monte Carlo simulation.
