We study how the combination of long and short laser pulses, can be used to induce torsion in an axially chiral biphenyl derivative (3,5-difluoro-3′,5′-dibromo-4′-cyanobiphenyl). A long, with respect to the molecular rotational periods, elliptically polarized laser pulse produces 3D alignment of the molecules, and a linearly polarized short pulse initiates torsion about the stereogenic axis. The torsional motion is monitored in real-time by measuring the dihedral angle using femtosecond time-resolved Coulomb explosion imaging. Within the first 4 picoseconds, torsion occurs with a period of 1.25 picoseconds and an amplitude of 3° in excellent agreement with theoretical calculations. At larger times the quantum states of the molecules describing the torsional motion dephase and an almost isotropic distribution of the dihedral angle is measured. We demonstrate an original application of covariance analysis of two-dimensional ion images to reveal strong correlations between specific ejected ionic fragments from Coulomb explosion. This technique strengthens our interpretation of the experimental data.

I. INTRODUCTION

The control of molecules and chemical reactions with lasers is one of the main goals of femtochemistry [1]. One particular aspect of such studies is the use of laser pulses to control the transition from one enantiomer of a chiral molecule to its mirror form. This topic has been the subject of a large number of theoretical studies and these efforts are motivated by the intriguing prospect of light-induced deracimization [2–8], i.e., creation of enantiomeric excess. Axially chiral molecules have attracted special interest because the potential barrier separating an enantiomeric pair is often low so that lasers at moderate intensities may be applied to facilitate efficient crossing of the barrier without fragmenting the molecule. For axially chiral molecules the stereogenic element is an axis (connecting two atoms) rather than a point (a single atom) and the reaction path separating the two enantiomers corresponds to torsion around the stereogenic axis [9].

The first theoretical light-based scheme which successfully showed the production of enantiomeric excess (50.0001% : 49.9999%) involved circularly polarized continuous wave monochromatic light [2]. However, a much higher conversion rate is needed if the deracimization is to be confirmed experimentally - not to mention to have practical applications. To this end studies showed that almost perfect deracimization could be achieved by exposing phosphinothioic acid (H₂OPSH) to picosecond terahertz laser pulses [3]. In these studies, the key was to realize that changes in the torsional coordinate was associated with a shift in the permanent dipole moment, a feature that was exploited by using polarization shaped laser pulses to transfer a racemate into the desired enantiomeric form. Since this discovery, several different approaches have been proposed to control torsional motion in axially chiral molecules. These approaches include the use of coherent control or phase controlled pulses [4] to perform, e.g., laser distillation [4] where excitation of one of the enantiomers can be enhanced by coupling the ground state to a superposition of two excited states with opposite parities, or by cyclic population transfer that relies on quantum interference in an effective three-level-system [5]. Alternatively, the deracimization can be achieved by exploiting that the direction of the electronic transition moment vector to an excited state is different for the two enantiomers. One way to exploit this directionality is a pump-dump scheme [6], where the population is gradually transferred from one enantiomer to the other. Another method would be asymmetric excitation, where the excited state is repulsive and leads to dissociation thereby removing this enantiomeric form from the ensemble [7]. A common feature for most of these schemes is that they either require or benefit from pre-aligned and oriented molecular targets [8].

Since alignment and orientation is generally required in the enantiomer-control-schemes a more straightforward, and thereby experimentally feasible approach, would be to rely on alignment concepts alone to control the torsion. Recently, this has been the focus of several studies. These studies fall into two regimes: (i) the adiabatic regime where the pump laser that induces torsion is long compared to the time scale of torsional dynamics [11] and (ii) torsion induced by a short non-adiabatic pump...
pulsed \[13\] [14]. For those axially chiral molecules where the stereogenic axis and the most polarizable axis coincide it was suggested that torsion could be controlled adiabatically by a single elliptically polarized nanosecond (ns) laser pulse provided that the torsional barrier is sufficiently low. This pulse potentially serves to both induce 3D alignment and torsional motion leading to a breakdown of the 1-dimensional (1D) adiabatic alignment with a linearly polarized 9 ns long laser pulse. In equilibrium the angle between the F-phenyl plane and the Br-phenyl plane is \(\pm 39^\circ\). Upon irradiation with a 700 femtosecond (fs) long, intense (but non-fragmenting), non-resonant pump pulse, torsion was induced accompanied by overall rotation around the fixed stereogenic axis. The torsional and rotational dynamics, measured by inducing Coulomb explosion with a short intense delayed probe pulse and recording of the emission direction of recoiling Br\(^+\) and F\(^+\) ions through ion imaging, showed that the amplitude and period of torsion was 0.6° and 1 picosecond (ps). While the period was in qualitative agreement with the theoretical model prediction of 1.2 ps, the amplitude predicted by theory was larger, 2.45°. The theory rationalized that stimulated Raman transitions, driven by the pump pulse, create a wave packet of torsional eigenstates in the electronic ground state leading to the torsion observed. It is one of the aims of the present work to resolve the discrepancy between theory and experiment.

The principle of the current work is similar to the previous work, \[13\] [14] but three key experimental factors were changed to achieve much better resolved peaks in the experimental ion images which allows for tracing of the torsional motion with unprecedented precision and, therefore, a quantitative rather than a qualitative comparison to the calculated results. The three decisive factors are: 1) A chemically much purer sample resulting in higher contrast ion images. 2) The molecules were 3D aligned \[14\] [17] prior to the kick and the probe pulses, i.e., the entire molecule was fixed-in-space not just the stereogenic axis (1D alignment). This implies that the torsional motion stands out much more distinctly in the ion images. 3) The molecule employed here, 3,5-difluoro-3',5'-dibromo-4'-cyanobiphenyl, is almost identical to the molecule studied in Refs. \[13\] [14] except that it has a nitrile group attached to the end of the Br-phenyl. This gives the current molecule a dipole moment of 4.4 Debye \[15\] compared to 0.2 Debye \[15\] for the molecule used previously. The large permanent dipole moment of the molecules made it possible to use an electrostatic deflector to spatially separate molecules according to their rotational quantum state \[19\] [20]. Performing the separation prior to the interaction with the laser pulses, allowed us to focus the laser pulses onto only the molecules with low rotational energy, improving the degree of prealignment \[19\] [20].

The paper is organized as follows. In Sec. II the experimental setup is described. In Sec. III the results are discussed and Sec. IV provides a comparison with theory. Section V concludes.

II. EXPERIMENTAL SETUP

The experimental setup has recently been described in detail \[21\] and only a brief description of the most important features is given here. A cold molecular beam (~1K) is formed by heating less than fifty milligram of solid 3,5-difluoro-3',5'-dibromo-4'-cyanobiphenyl in 90 bar of He to 170°C and expanding the mixture into vacuum through a pulsed Even-Lavie valve. This chemical is not commercially available and was synthesized specially for the experiment (see Appendix). Here it should be noted that in the previously reported experiment the molecular sample was slightly contaminated which can be seen directly from close inspection of the NMR spectrum in Fig. 4 (d) of \[15\]. In particular the NMR spectrum shows a small impurity (5%) of the biproduct where both phenyl rings have fluorine substituents. This contamination is problematic since the vapor pressure of the biproduct is higher than the target molecule and, therefore, the ratio between impurity and target molecules will be higher in the molecular beam than the initial 5% in the powder sample. Furthermore, the second most polarizable axis of the impurity will be located halfway between the two phenyl rings and, therefore, contribute to significant blurring of the F\(^+\) ion images and, thus, reduce the capability to experimentally resolve the torsional motion.

The beam of cold molecules pass through an electrostatic deflector that deflects the molecules according to their effective dipole moment. The effective dipole moment is determined by its rotational quantum state \[20\]. Following deflection, the molecules enter a velocity map imaging (VMI) spectrometer (Fig. 1) where they are irradiated by three pulsed laser beams. The first pulse (YAG pulse: \(\lambda = 1064\) nm, \(\tau_{\text{FWHM}} = 10\) ns, \(I_{\text{YAG}} = 6 \times 10^{11}\) W/cm\(^2\)) serves to adiabatically align the molecules. It is elliptically polarized with the major axis parallel to the spectrometer axis, the Z-axis (see Fig. 1). The second pulse (kick pulse: 800 nm, 200 fs, \(I_{\text{kick}} = 2 \times 10^{12}\) W/cm\(^2\)) initiates torsion and it is linearly polarized along the Y-axis. The third pulse (probe pulse: 800 nm, 30 fs, \(I_{\text{probe}} = 3 \times 10^{14}\) W/cm\(^2\)) is used to characterize the spatial orientation of the two phenyl planes by Coulomb exploding the molecules and recording the recoiling F\(^+\) and Br\(^+\) fragments. It is linearly polarized either along the Z-axis or the Y-axis. By recording series
of images for different kick-probe delays, $t$, the evolution of the torsional motion can be monitored. To ensure that the molecules probed are both aligned and torsionally excited, the spotsize of the three laser pulses are adjusted such that the foci of the YAG and kick pulses are large ($\omega_0 = 38 \mu m$ and $\omega_0 = 35 \mu m$) compared to the probe pulse ($\omega_0 = 26 \mu m$).

III. EXPERIMENTAL RESULTS

A. Deflection

The effect of the deflector on the molecular beam is shown in Fig. 2 by the vertical intensity profiles. They are obtained by recording the magnitude of an ion signal, produced by the probe pulse only, as a function of the vertical position of the laser focus similar to what was previously reported (see, for instance, Refs. [17, 19, 21]). Here, we use the strongest peak in the ion time-of-flight-spectrum which is the C$^+$ signal. When the deflector is off, the molecular beam extends over $\sim 1.5$ mm, mainly determined by the diameter of the skimmer before the deflector. When the deflector is turned on, the molecular beam profile broadens and shifts upwards (positive Y-values). The molecules in the lowest rotational quantum states have the largest effective dipole moments and are, therefore, deflected the most, as shown in recent work on iodobenzene and benzonitrile molecules [19, 20]. In the measurements described below, experiments were conducted on quantum state-selected molecules simply by positioning the laser foci close to the upper cut-off region in the 10 kV profile, indicated by the red arrow in Fig. 2 ($Y = 1.3$ mm). Our motivation for using the deflected part of the beam is that despite the density of molecules is lower, the alignment is higher [17, 19, 20].

B. Adiabatic prealignment

The 3,5-difluoro-3′,5′-dibromo-4′-cyanobiphenyl (C$_{13}$H$_5$F$_2$Br$_2$N, to be denoted by DFDBrCNBph in the following) is a chiral asymmetric top molecule, and the molecular composition in the supersonic expansion is a racemate, i.e., consisting of 50% of each of the two enantiomers.

Three-dimensional alignment of the molecules is achieved using an elliptically polarized YAG pulse which confines both the most polarizable axis (MPA) and the second most polarizable axis (SMPA) of the molecule [16, 17, 22, 23], respectively. In DFDBrCNBph the MPA is located along the stereogenic axis (C-C bond axis connecting the two phenyl rings – see Fig. 1) whereas the SMPA is perpendicular to this at an angle of 10° from the phenyl-plane with the nitrile and bromine substituents towards the other phenyl ring (see Fig. 4). The effect of applying the YAG pulse, having its major and minor polarization axis along the Z-axis and the Y-axis, respectively, can be seen in panels (a) and (b) at $t = -0.33ps$ in Fig. 3 showing F$^+$ and Br$^+$ ion images from Coulomb exploding the molecules at the peak of the YAG pulse. In both images two distinct features are observed. First, the center of the detector is almost void of ions (a minor region has been cut in the F$^+$ images to exclude a noise signal from residual water molecules in the chamber). This observation is only compatible with the stereogenic axis (C-C bond axis) being confined perpendicular to the detector plane, i.e., along the Z-axis. Secondly, it is seen that both the Br$^+$ and the F$^+$ ions localize around the minor polarization axis of the YAG pulse (the Y-axis), the confinement being more pronounced for the Br$^+$ ions. We interpret this as the SMPA of the molecule being
aligned along the Y-axis. The more spread-out signal of the F\textsuperscript{+} ions results from the fact that the F-phenyl ring, at equilibrium, is offset 28° from the SMPA whereas the Br-phenyl ring is only offset by 10°. Thus, the joint observations of the F\textsuperscript{+} and Br\textsuperscript{+} images demonstrate that the molecules are 3D aligned as expected.

C. Time-dependent Torsion

To investigate the torsional motion induced by the kick pulse we recorded series of both F\textsuperscript{+} and Br\textsuperscript{+} images at different kick-probe delays. The probe pulse was polarized perpendicular to the detector plane to ensure a detection efficiency that is independent of the orientation of the F- and Br-phenyl-rings. The results are shown in panels A and B of Fig. 3. The first striking observation is that from 0.67 ps to 4.0 ps the F\textsuperscript{+} images develop a pronounced 4-peak structure consisting of a pair in the top and a pair in the bottom part of the images. This shows that the kick pulse sharpens the alignment of the SMPA in agreement with a recent study on naphthalene where it was demonstrated that the combined action of 3D adiabatic prealignment and a short kick pulse could significantly improve the alignment of the molecular plane in a time interval shortly after the kick pulse \cite{24}. The second observation is that the angular separation of the two regions in each F\textsuperscript{+} pair oscillates as a function of time. At \( t = 1.33 \) ps the angular separation reaches a local minimum, at \( t = 2.0 \) ps a local maximum, at \( t = 2.67 \) ps a local minimum etc. Turning to the Br\textsuperscript{+} ion images it is seen that the confinement along the Y-axis (vertical) improves. Unlike the F\textsuperscript{+} images a clear 4-peak structure is not observed. We ascribe this to the fact that the Br-phenyl ring is much closer to the SMPA, i.e., Br\textsuperscript{+} ions from molecules with the Br-phenyl ring localized on each side of the SMPA will overlap and prevent a distinct 4-peak structure. It is, however, observed that the width of the Br\textsuperscript{+} oscillates as a function of time in phase with that observed in the F\textsuperscript{+} images. These joint observations show that the dihedral angle between the Br-phenyl ring and the F-phenyl ring changes as a function of time. In other words, the torsional motion is directly imprinted on the ion distributions recorded.

The contrast can be improved significantly by recording the F\textsuperscript{+} and Br\textsuperscript{+} images with the probe pulse polarized parallel to the kick pulse polarization. These data are displayed in Fig. 3 panels (c) and (d). The evolution of both ion species is the same as that observed in rows (a) and (b), but the contrast is significantly higher. In particular, the 4-peak structure in the F\textsuperscript{+} images is very distinct with complete separation between the two regions in each pair and the oscillations in the angular width of the Br\textsuperscript{+} images stand out very clearly. Our qualitative understanding of the improved contrast is that the probe pulse preferentially ionizes molecules with their SMPA close to its polarization axis. In other words, the probe pulse selects the molecules with the strongest alignment of the SMPA.

The quantitative analysis is performed by fitting the angular distributions, extracted from the ion images, with a sum of four Gaussian functions. From these fits, the average angles, \( \langle \phi_{F+} \rangle \), of the Br-phenyl ring, with respect to the kick pulse polarization, can be extracted directly, from the peak positions of the Gaussian functions. Similarly, the average angle, \( \langle \phi_{Br+} \rangle \), of the F-phenyl-ring can be found from the fit of the F\textsuperscript{+} angular distributions.

Figure 4 displays the average angle between the F-phenyl-rings (black squares) and the kick pulse polarization as a function of kick-probe time delay for the time interval where a clear four-peak-structure can be identified in the angular distributions. The dashed black line splined to the experimental measurements indicates that the oscillations observed in the images of the F-phenyl ring have an amplitude of \( \sim 2.5° \) with respect to the kick pulse polarization direction and a period of 1.25 ps. Closer examination of the oscillating trace reveals a small overall increase towards larger \( \langle \phi_{F+} \rangle \) which shows that the plane of the F-phenyl-ring slowly moves away from the kick pulse polarization. Also the average angle between the Br-phenyl-rings (red circles) and the kick pulse polarization is shown. In the time interval 1–4 ps the uncertainties on the measurements are small and allows for determination of the period (1.25 ps) and amplitude (\( \sim 0.5° \)) of the motion. For the Br-phenyl-ring, we observe a small decrease in \( \langle \phi_{Br+} \rangle \) with increasing time delay. The slight decrease in \( \langle \phi_{Br+} \rangle \) and corresponding increase in \( \langle \phi_{F+} \rangle \), are fully compatible with an overall rotation of the molecule about the stereogenic axis.

The average values, \( \langle \phi_{F+} \rangle \) and \( \langle \phi_{Br+} \rangle \), can be used to calculate the instantaneous dihedral angle, \( \phi_{4z} \), of the molecule by simple addition (see Fig. 3 (b)). By retrieving these average values at every kick-probe time delay it is possible to directly monitor the evolution of the dihedral angle of the molecule. The results for the dihedral angle (\( \phi_{4z} \), blue triangles) are displayed in Fig. 4 (a), with a dashed line included to help guide the eye and emphasize the torsional motion. The oscillation is seen to have an amplitude of 3° and a period of 1.25 ps.

We also recorded F\textsuperscript{+} and Br\textsuperscript{+} ion images for times larger than 4 ps. The results, including the 3.0 ps data, are shown in Fig. 5. For \( t > 4.0 \) ps the F\textsuperscript{+} ion images loose their distinct four region structure and, instead, evolve into a circular shape at \( t \geq 8 \) ps. This prevents tracking the evolution of \( \langle \phi_{F+} \rangle \). The images, however, confirm that the stereogenic axis of the molecule is still tightly confined along the major axis of the YAG polarization ellipse, since the central region is absent from ions. The corresponding Br\textsuperscript{+} ion images show a similar delocalization behavior, but the broadening is slower. This observation is consistent with theory as discussed in Sec. IV B.

To quantify the time-dependence of the delocalization in the F\textsuperscript{+} and Br\textsuperscript{+} ion images we determined for each image \( \cos^2 \alpha_{2D} \), where \( \alpha_{2D} \) is the angle between the projection of an ion velocity vector on the detector plane
FIG. 3. F⁺ (panel (a) and (c)) and Br⁺ (panel (b) and (d)) ion images obtained as a function of the kick-probe time delay indicated in ps above each column of panels. Panels (a) and (b) ((c) and (d)) were obtained using a linearly polarized probe pulse being perpendicular to (parallel with) the detector. The delay of the probe pulse (λ = 800 nm, τ_FWHM = 30 fs, I_{probe} = 3 × 10^{14} W/cm²) with respect to the kick pulse (λ = 800 nm, τ_FWHM = 200 fs, I_{kick} = 2 × 10^{13} W/cm²) is given by the numbers on the top of the vertical panels.

FIG. 4. (a) Time-dependence of the dihedral angle (blue triangles) following the kick-pulse, obtained by adding the orientation of the F-phenyl-ring (black squares) and the orientation of the Br-phenyl-ring with respect to the SMPA – see text for details. (b) Sketch of the molecular structure as seen in end view. The SMPA of the molecule and the extracted angles are marked on the drawing.

FIG. 5. F⁺ (a) and Br⁺ (b) ion images obtained at long (t ≥ 3 ps) kick-probe time delays obtained using a probe pulse linearly polarized perpendicular to the detector. The delay of the probe pulse (λ = 800 nm, τ_FWHM = 30 fs, I_{probe} = 3 × 10^{14} W/cm²) with respect to the kick pulse (λ = 800 nm, τ_FWHM = 200 fs, I_{kick} = 2 × 10^{13} W/cm²) is given by the numbers on the top of the vertical panels.

FIG. 6. Time dependence of the planar alignment of the individual phenyl-rings. The ⟨cos² α_{2D}⟩ values are calculated from rotated angular distributions to remove the effect of the torsion (see text for details). Black squares (red circles) correspond to the confinement of the F-phenyl-ring (Br-phenyl-ring).

and the Y-axis (See Fig. 7). This is implemented by rotating the peaks fitted to the angular distributions of F⁺ and Br⁺ ions, towards the Y-axis by the following procedure: If the peak is located in the first or third quadrant the F⁺ (Br⁺) image is rotated by −⟨φ_{F⁺}⟩ (−⟨φ_{Br⁺}⟩) before calculation of ⟨cos² α_{2D}⟩, whereas if the peak is in the second or fourth quadrant the image is rotated by +⟨φ_{F⁺}⟩ (+⟨φ_{Br⁺}⟩). This procedure allows for calculation of the best estimate of the spread from the mean by including all data. The ⟨cos² α_{2D}⟩ values are displayed in Fig. 6. A clear difference in the delocalization dynamics of the two phenyl planes is observed, with the light
fluorine substituted phenyl ring approaching \(\langle \cos^2 \alpha_{2D} \rangle = 0.5\) more rapidly than the heavier bromine substituted phenyl ring. This is fully consistent with semi-classical theoretical predictions presented in Sec. IV B.

**D. Covariance and Autovariance Mapping**

Before discussing the theoretical results we introduce covariance mapping analysis \(^{25}\) to the experimental data. This analysis strengthens our interpretation of torsional motion, based on the fluorine and bromine ion images in \(\text{Fig. 3}\). Covariance mapping is a technique to reveal correlations, which in the high count rate regime would otherwise become blurred or completely lost due to the large contributions from uncorrelated events. The basic principle is to calculate the covariance, i.e., to obtain a crosscorrelation of the variance in the data \(^{26}\), to extract the deviation from the mean value for all the individual frames of the ion image, pertaining to each (probe) laser shot. This is fundamentally different from coincidence measurements in, e.g., COLTRIMS and reaction-microscopes \(^{27, 28}\) where the count rate is restricted to less than one event per laser shot, since the covariance map is produced from the correlations of the variance, which per definition has no restrictions on the number of events obtained per laser shot.

The covariance \(\langle C(x, y) \rangle\) between two observables \(X(x)\) and \(Y(y)\) is defined as the mean of the product between the observables \(\langle X(x)Y(y) \rangle\) subtracted by the product of the means \(\langle X(x) \rangle \langle Y(y) \rangle\):

\[
C(x, y) = \langle (X(x) - \langle X(x) \rangle)(Y(y) - \langle Y(y) \rangle) \rangle \\
= \langle X(x)Y(y) \rangle - \langle X(x) \rangle \langle Y(y) \rangle \tag{1}
\]

Here \(X\) and \(Y\) correspond to the observed signals, with \(x\) and \(y\) being the variables investigated for correlation.

Although many different correlation techniques have been explored previously and found many different applications within natural science \(^{28, 31}\), to our knowledge no reports on using covariance mapping to extract angular correlation information from 2D ion images has been reported. We suggest to do this by replacing \(X\) and \(Y\) with \(\Theta\) and \(\Xi\), corresponding to the angular distributions of the ion signal, and \(x\) and \(y\) with \(\theta\) and \(\xi\) being the ion detection angle with respect to the Y-axis \(\text{Fig. 1}\). Applying this version of covariance mapping to the impact coordinates of the ions in the 2D velocity map images, allows for extraction of the angular correlation between ejected fragments. In our experiment only one ion species, e.g., \(F^+\), is detected per laser shot and thus \(\Theta = \Xi\). As a consequence Eq. (1) may be written as

\[
C(\theta_1, \theta_2) = \langle \Theta(\theta_1)\Theta(\theta_2) \rangle - \langle \Theta(\theta_1) \rangle \langle \Theta(\theta_2) \rangle \\
= \frac{1}{N} \sum_{i=1}^{N} \Theta_i(\theta_1)\Theta_i(\theta_2) \\
- \frac{1}{N} \sum_{i=1}^{N} \Theta_i(\theta_1) \left[ \frac{1}{N} \sum_{i=1}^{N} \Theta_i(\theta_2) \right] \tag{2}
\]

Since this corresponds to investigating correlations of a signal with itself this approach is equivalent to obtaining an autocorrelation of the variance in the data and so the 2D maps depicting the correlation should be termed autovariance maps. The principle of autovariance mapping is illustrated in \(\text{Fig. 7}\). Following each laser shot the ions focused onto the detector are recorded by a CCD camera after which an image analysis program saves the impact coordinates, illustrated by the yellow bars in the image analysis box. The experiment is repeated \(N\) times, typically \(N = 10.000\), giving the averaged ion images (such as those shown in \(\text{Fig. 3}\)) with the averaged angular distributions \(\text{Fig. 7}\) (dashed black line). The autovariance \(C(\theta_1, \theta_2)\) can now be determined by applying Eq. (2) to all \(N\) frames of the ion image, and displayed as a 2D map of the ejection angles. In this map the two axes correspond to the angular distribution from the averaged image, with the positive Y-axis denoting \(0^\circ\).

Autovariance maps obtained through this procedure will tend to produce a strong autocorrelation line along the diagonal of the map, since the observation of an ion in frame \(\Theta_i\) at the angle \(\theta_i\) is naturally also observed in the same frame, for the identical observable \(\Theta_i\), at \(\theta_2 = \theta_1\). This autocorrelation trace will also act as an axis of symmetry for the correlation, since \(C(\theta_1, \theta_2) = C(\theta_2, \theta_1)\), which is in fact equivalent to the square of the r.m.s. standard deviation by definition. The positive areas of the autovariance maps, which fall outside the autocorrelation line \(\langle \theta_1 \neq \theta_2 \rangle\), indicate the correlation between...
ions at $\theta_1$ and $\theta_2$, showing an increased likelihood of observing an ion at $\theta_2$ provided that an ion is detected at $\theta_1$.

Figure 8 shows the angular autovariance maps obtained from both F$^+$ and Br$^+$ ion images at two different kick-probe time delays. In these maps the dominant autocorrelation signal along the diagonal has been set to zero to increase the contrast of the interesting but less intense correlations in the autovariance map. Also these data sets have been binned in steps of 5° to smooth out small fluctuations. A striking feature of all autovariance maps is that the observed correlations are restricted to areas where the angle between the ejected ions is close to 180°. This is seen, e.g., in the F$^+$ map at 2 ps, where the signal at $\approx 150^\circ$ ($\approx 210^\circ$) is correlated to the region at $\approx -30^\circ$ ($\approx -30^\circ$). In other words, when an F$^+$ ion is ejected upwards at an angle of 150° there is a high probability that another F$^+$ ion is ejected at -30°, i.e., just in the opposite direction. This corroborates our interpretation of the two ion species as direct observables of the orientation of each of the phenyl rings. In addition, the observation of four prominent positive areas in the autovariance map at $t = 2$ ps confirms the interpretation of the 4-peak structure in the F$^+$ ion images [Fig. 3]. Similar considerations hold for the Br$^+$ autovariance map at $t = 2$ ps.

Notably the appearance of a 4-peak structure with positive covariance shows even clearer than the averaged ion image on Fig. 3 that the Br-phenyl plane has a small angular offset with respect to the kick pulse polarization. At $t = 10$ ps there is no longer a 4-peak structure but the distinct oblique lines show unambiguously that emission of both F$^+$ and Br$^+$ ions still occurs in a pairs with an upward and a downward ion. The extension of the covariance principle to obtain angular correlation between ions allows for the extraction of additional information from the 2D images obtained using VM3 spectrometers. As shown here, a single detector setup, can be used to obtain autovariance maps between ions of identical mass-to-charge ratios, which can be used to both substantiate and clarify the interpretation of the recorded ion images. This can be extended to obtain the correlation between ions with different mass-to-charge ratios by pulsing the front of the MCP twice per laser shot and running the CCD camera in burst mode. In addition, we note that the technique can also be extended to obtain radial autovariance maps, for fragmentation processes with multiple energy channels, or combined to encompass both angular and radial correlation of the 2D ion images.

IV. COMPARISON WITH THEORY

The main findings of Sec. III were that the dihedral angle oscillates with a period of approximately 1.25 ps, and an amplitude of 3°. These findings were based on an analysis of the data assuming that the two ion species move out to the detector in the plane of the (substituted) phenyl ring from which they originated. The covariance and autovariance analysis introduced validated this assumption and we may build the theory on this fact.

A. Early time dynamics: Torsional motion

The purpose of this section is to provide a theoretical foundation for understanding the experimentally observed ion images shown in Fig. 3. Atomic units ($|e| = \hbar = m_e = a_0 = 1$) are used throughout. A useful starting point is to discuss the widths of the ion images. These may conveniently be quantified in terms of the variance

$$\sigma_i^2 = \langle \phi_i^2 \rangle - \langle \phi_i \rangle^2, \quad i = \text{Br}^+, \text{F}^+. \quad (3)$$

For the sake of interpretation, we rewrite these two angles in terms of the dihedral angle, $\phi_d$, and the overall rotation, $\Phi$ [see Fig. 4(b)].

$$\phi_{\text{Br}^+} = \Phi + \eta \phi_d, \quad (4)$$
$$\phi_{\text{F}^+} = \Phi - (1 - \eta) \phi_d, \quad (5)$$
$$\eta = \frac{I_{\text{F}^+}}{I_{\text{F}^+} + I_{\text{Br}^+}}. \quad (6)$$

Consequently, we may express the variance of the ob-
It is therefore obvious to ask if the dihedral angle is small (see Figs. 3 and 9 in Ref. [15]). For shorter times, however, the widths of the two ion images are close (see Fig. 3). Further, we have previously argued for separability of the $\Phi$ and $\phi_d$ coordinates in this limit [15] meaning that the last term in Eqs. (7) and (8) vanishes completely. In this regime $\Phi$ is an adiabatic parameter and we simply discuss the torsional motion. The torsional potential from one molecule to the other breaks down [12, 15]. It follows that we may simply shift the previously calculated theoretical curve by $-0.9^\circ$ to match the dihedral angle of DFDBrCNBPh at equilibrium.

Previous investigations show that the variance of the dihedral angle is small (See Figs. 3 and 9 in Ref. [15]). We will now use this approximation to derive the evolution of the torsional state $\psi_{\phi_d}(t)$. The torsional potential — essentially simple harmonic oscillation of the rings $i = Br^+$ — consists of small, periodic oscillations. As follows from (12) that this coherence beats like

$$\cos \left( \frac{2J_i + 1}{2I_i} t \right)$$

We solve this equation for DFDBrBPh using a close coupling method with a value of $\Phi$ corresponding to the SMPA and kick pulse polarization aligned. As initial state $\Psi(\phi_d, t_0)$, we use a state localized in the torsional well at $39^\circ$. The details have been given in Ref. [15].

Figure 9 shows the result of the calculation. The torsional dynamics consist of small, periodic oscillations. As argued previously [15], these oscillations stem from the fact that the kick pulse leaves DFDBrBPh in a coherent superposition of the ground state and first excited state of the torsional potential — essentially simple harmonic oscillator states separated by 3.42 meV. The molecule used in the experiment is DFDBrCNBPh rather than DFDBrBPh. The torsional potential differs, however, only slightly from that used previously for DFDBrBPh. Since the kick pulse only populates the first few torsional states where the potential is very close to harmonic, the main effect to take into account is the shift of the minima of the torsional potential from one molecule to the other ($-0.9^\circ$). It follows that we may simply shift the previously calculated theoretical curve by $-0.9^\circ$ to obtain a comparison with the experimental results. As seen in Fig. 9 this leads to an impressive agreement with the experimental results.

### B. Long time behavior: Dephasing of the phenyl rings

For longer time scales ($t > 3$ ps), the semi-classical model is no longer attractive. The reasons are that the widths of the two ion images (Figs. 3 and 5) start to deviate from one another meaning that the variance is no longer dominated by $\Phi$ alone and, hence, that the separability in $\Phi$ and $\phi_d$ breaks down [12, 15].

To provide a qualitative analysis in this long-time regime, we exploit a different theoretical limit, where the phenyl-rings are treated as rigid rotors. In this case, each of the rings $i = Br^+$, $F^+$ can be described by a wave packet

$$\Psi_i(\phi_i, t) = \sum_{J_i} c_{J_i} \frac{1}{\sqrt{2\pi}} e^{iJ_i\phi_i} e^{-J_i^2 \frac{\pi^2 t^2}{4}} \text{,}$$

where $J_i$ labels a rotational state and where $c_{J_i}$ is a fixed constant after the end of kick pulse.

To estimate on what time scale, $\tau$, such a wave packet dephases, we look at the time evolution of the coherence between two neighboring levels $J_i$ and $J_i + 1$. It immediately follows from (12) that this coherence beats like
Consequently, the two rings dephase at a ratio

\[ \frac{r}{r_{\text{Br}^+}} = \frac{I_{\text{F}^+}}{I_{\text{Br}^+}} \cdot \frac{2J_{\text{Br}^+} + 1}{2J_{\text{F}^+} + 1} \]  

(14)

The value of \( J_i \) depends on the rotational kinetic energy, \( E_{\text{kin,i}} \), of each ring. Due to the \( a \) times higher polarizability of the Br-phenyl-ring compared to the F-phenyl-ring, we assume that \( E_{\text{kin,Br}} = a \times E_{\text{kin,F}} \) with \( E_{\text{kin,i}} = J_i^2 / 2I_i \). This result is achieved by integrating the torque of a classic rigid rotor from 0° to 90° to obtain an energy estimate. We then immediately have

\[ \frac{J_{\text{Br}^+}}{J_{\text{F}^+}} = \sqrt{\frac{a}{I_{\text{Br}^+}} / I_{\text{F}^+}} \]  

(15)

Using this in Eq. (14) yields

\[ r \simeq \sqrt{\frac{a}{I_{\text{Br}^+}} / I_{\text{F}^+}} \]  

(16)

With a value of 0.21 for the ratio of the moments of inertia and \( a = 2 \) [18], we obtain \( r = 0.65 \) in qualitative agreement with the dephasing ratio of 0.68 obtained from the data presented in Fig. 6 by comparing the full width at half maximum values of the Gaussian fits to the ion pictures.

### V. CONCLUSIONS

In conclusion we have shown that it is possible to induce torsion in a substituted biphenyl molecule with a nonresonant kick pulse and image the motion in real-time with an intense delayed probe pulse. The measurements show a distinct torsional motion with an amplitude of 3° and a period of 1.25 ps for the first 4 ps after the kick pulse, in excellent agreement with results from our theoretical model. At longer times delocalization of the two phenyl rings of the molecule blurs torsion.

An important prerequisite for the experiment is the ability to keep the molecules fixed-in-space during the time-resolved experiment, practically obtained by 3D aligning them in the adiabatic limit. This places both benzene rings of the molecule perpendicular to a 2D imaging detector. Upon Coulomb explosion by the probe laser \( \text{Br}^+ \) ions from one benzene ring imprint an ion image on the detector screen that uniquely identifies the orientation of this ring. Likewise, \( \text{F}^+ \) ion images identify the orientation of the second ring. The difference between the orientation of the two rings determines the dihedral angle, i.e., the normal vibrational coordinate characterizing torsion. Such a procedure would not be possible for samples of randomly oriented molecules.

The paper also showed that it is possible to apply covariance mapping analysis of ion images. This revealed clear correlations between the emission direction of ions strengthening our interpretation of Coulomb explosion as a direct and unique observable of molecular orientation. Covariance and autovariance methods applied to ion imaging have a potential to provide additional information beyond what is normally extracted from averaged quantities.

### VI. ACKNOWLEDGEMENT

### APPENDIX

**Synthesis of 3,5-difluoro-3′,5′-dibromo-4′-cyanobiphenyl**

3,5-Difluoro-4′-aminobiphenyl: [32] To a sample vial was added 4-bromoaniline (172.0 mg, 1.0 mmol), 3,5-difluorophenyl boronic acid (189.5 mg, 1.2 mmol), tributylammonium bromide (32.4 mg, 0.1 mmol), potassium carbonate (276.4 mg, 2 mmol) and water (2 mL). To this was added 100 µL of a PdCl₂:EDTA:Na₂CO₃ stock solution prepared by mixing PdCl₂ (17.7 mg, 0.1 mmol), EDTA (37.2 mg, 0.1 mmol) and Na₂CO₃ (21.2 mg, 0.2 mmol) in water (1 mL). The vial which was fitted with a Teflon sealed screwcap and heated to 100°C for 45 min after which the reaction was cooled to room temperature. The mixture was diluted with Et₂O (25 mL) and CH₂Cl₂ (10 mL). The organic phase was washed with water (2×15 mL), brine (15 mL) and dried using MgSO₄. The solvents were removed under reduced pressure and the crude reaction mixture was purified by column chromatography eluting with CH₂Cl₂ to afford the title compound as a colorless solid (170.5 mg, 83%). 1H NMR (400 MHz, CDCl₃) δ (ppm) 7.37 (d, 2H, J = 8.2 Hz), 7.07-7.00 (m, 2H), 6.74 (d, 2H, J = 8.2 Hz), 6.69 (tt, 1H, J = 8.8, 2.3 Hz), 3.79 (bs, 2H). 13C NMR (400 MHz, CDCl₃) δ (ppm) 163.6 (dd, J = 245.0, 13.2 Hz), 147.3, 144.8 (t, J = 9.6 Hz), 129.1 (t, J = 2.5 Hz), 128.2, 115.6, 109.1 (dd, J = 18.4, 6.9 Hz), 101.5 (t, J = 25.4 Hz). 19F NMR (376 MHz, CDCl₃) δ (ppm) -110.8 (t, J = 8.8 Hz). HRMS. C₂₃H₁₃F₂N [M+H⁺] Calculated: 308.0781. Found: 308.0780.

3,5-Difluoro-3′,5′-dibromo-4′-aminobiphenyl: [33] 3,5-Difluoro-4′-aminobiphenyl (165.0 mg, 0.8 mmol) was dissolved in glacial acetic acid (2.5 mL). Bromine (82 µL, 255.7 mg, 1.6 mmol) dissolved in glacial acetic acid (3.8
reaction mixture was cooled to 10 °C. Concentrated sulfuric acid (1.0 mL) was added and the aminobiphenyl (270.0 mg, 0.74 mmol) was dissolved in the reaction mixture. 3,5-Difluoro-3′,5′-dibromo-4′-cyanobiphenyl: Reaction mixture 1: 3,5-Difluoro-3′,5′-dibromo-4′-aminobiphenyl (270.0 mg, 0.74 mmol) dissolved in a minimum of water (1.0 mL) and glacial acetic acid (3.7 mL). Concentrated sulfuric acid (1.0 mL) was added and the reaction mixture was cooled to 10°C. Sodium nitrite (56.5 mg, 0.82 mmol) dissolved in a minimum of water was slowly added and the reaction was left stirring for 30 min at which point the reaction mixture had become clear. Reaction mixture 2: In a second round bottom flask CuSO₄•5H₂O (223 mg, 0.89 mmol) is carefully mixed in water (1 mL) with KCN (242 mg, 3.72 mmol) dissolved in water (1 mL) keeping the temperature below 20°C cooling with ice. To reaction mixture 2 is slowly added reaction mixture 1 while keeping the reaction basic by adding Na₂CO₃ (sat.). After the addition is complete the reaction is left stirring 1 hour at room temperature. CH₂Cl₂ (30 mL) and Et₂O (50 mL) are added and the organic phase was washed with water (2×20 mL), brine (20 mL) and dried using MgSO₄.

The solvents were removed under reduced pressure and the crude reaction mixture was purified by column chromatography eluting with pentane:CH₂Cl₂ 3:1 to afford the title compound as a colorless solid (141.8 mg, 75%).

3:1. 1H NMR (400 MHz, CDC13) δ (ppm): 7.59 (s, 2H), 7.01-6.96 (m, 2H), 6.92 (tt, 1H, J = 8.6, 2.3 Hz). 13C NMR (100 MHz , CDCl3) δ (ppm) -109.8 (t, J = 8.5 Hz). GCMS. C₁₂H₁₂F₂NBr₂ Calculated: 362.99 Found: 363 (100), 213 (68), 186 (15), 106 (15).

[18] Dipole moments and polarizabilities were computed with TURBOMOLE 6.2 [34] at density functional theory (DFT) level, employing the B3LYP functional which combines Becke’s three-parameter hybrid exchange functional [35] with the Lee-Yang-Parr correlation functional [36]; the correlation of the uniform electron gas was modeled with the Vosko-Wilk-Nusair VWN5 formulation [37]. The doubly-polarized triple-zeta basis set, TZVPP, [38] was used throughout. This level of theory has been shown to be suitable for the study of biphenyls [39].
