bles of life\(^{(6-7)}\), with a slight predilection for males and prefer-
ential involvement of the sacrococcygeal region (50\%), followed
by the spheno-occipital region (35\%), cervical spine, and lumbar
spine, occurring only rarely in the dorsal spine and posterior
mediastinum\(^{(6-8)}\). Symptoms often appear only after the lesion
has reached large proportions, with local invasion affecting neu-
rovascular structures. Local recurrence is common when com-
plete resection was not possible.

The differential diagnoses of chordoma include metastases, chondrosarcoma, multiple myeloma, neurogenic tumors, among
others. Although imaging methods help delineate the lesion, the
diagnosis is made on the basis of the histopathological analysis\(^{(7)}\).

On MRI, most chordomas show isointense or hypointense
signals in T1-weighted sequences, whereas they show hyperin-
tense signals in T2-weighted and short-tau inversion-recovery
sequences, reflecting their high water content, some lesions con-
taining fibrous septa and therefore showing low signal intensity
in T2-weighted sequences\(^{(6-8)}\). Gadolinium contrast enhance-
ment tends to be moderate and heterogeneous\(^{(6-8)}\). Lesions are
often accompanied by bone erosion, which was not observed
in the case reported here. Recent studies have highlighted the
use of diffusion-weighted imaging in the differentiation between
chordomas and chondrosarcomas, reporting that the latter show
higher apparent diffusion coefficients\(^{(9,10)}\).

In addition to an unusual site of involvement, our patient
presented the peculiarity of a synchronous lesion. Although
some authors have reported similar cases\(^{(7,8,11,12)}\), there is no
specific criterion for differentiating between a multicentric
chordoma and metastatic dissemination. We believe that our
case could represent dissemination to the cerebrospinal fluid,
because there was involvement of the vertebral canal.

The treatment of choice for chordoma is surgical resection
with adjuvant radiotherapy, resulting in a disease-free period
approximately 2.5 years longer than that achieved after surgi-
cal treatment alone\(^{(7)}\). Because chordoma is resistant to con-
tventional radiotherapy, other modalities, such as stereotactic
radiosurgery, are used. Chordoma does not respond well to che-
motherapy, antitumor activity having been observed, in small
studies, only with the use of imatinib mesylate\(^{(13)}\).

Albeit rare, a diagnosis of chordoma should be considered
in patients with lesions affecting the posterior mediastinum. In
addition, the possibility of synchronous lesions should be inves-
tigated in such patients.

Esthesioneuroblastoma

Dear Editor,

A 64-year-old male presented with nasal obstruction, anos-
ia, and a reduction in visual acuity over the last few months,
together with weight loss and a two-year history of headache.
Computed tomography (CT) of the brain (Figure 1A) showed an
expansile lesion with poorly defined borders, occupying the
ethmoid cells, sphenoid sinuses, and the anterior cranial fossa,
accompanied by edema of the frontal lobes. On magnetic reso-
nance imaging (MRI) scans (Figures 1B, 1C, and 1D), the
lesion showed restricted diffusion and intense enhancement after
contrast administration. A biopsy was performed, and analysis of
the biopsy sample revealed hyperchromatic cells organized
around a fibrillar stroma, forming rosettes, consistent with a di-
agnosis of esthesioneuroblastoma. The lesion was staged his-
tologically as grade I in the Hyams grading system. There was
no evidence of cervical involvement or distant metastases. The
patient died 15 days after undergoing the examinations.

Olfactory neuroblastoma, also known as esthesioneuro-
blatoma, is a rare malignant neoplasm of neuroectodermal origin
and accounts for 3–6% of all malignant tumors of the paranasal
sinuses. It has a bimodal age distribution, being most common
among adults in the second or fifth decades of life\(^{(1)}\). It is be-
thought that the neoplasm arises from the olfactory epithelium, origi-
nating in the superior portion of the nasal cavities, ascending
across the cribriform plate, and extending into the anterior cra-
nial fossa\(^{(2)}\).

Clinically, olfactory neuroblastoma manifests as nasal ob-
struction or epistaxis. It can show indolent behavior, promote
local invasion, and generate distant metastases. It tends to in-
vade the paranasal sinuses, orbits, and anterior cranial fossa.
The most common metastases are to the lymph nodes of the
neck, lungs, liver, and bone, such dissemination at the time of
diagnosis being the main predictor of survival\(^{(2)}\). Although there
is no universally accepted staging system, the Kadish classifica-
tion system, established in 1976 and considered an important
prognostic predictor, is widely used. In the Kadish system, stage

that of muscle tissue) hypointense in T1-weighted sequences

olfactory neuroblastomas present a signal that is (in relation to intracranial and orbital involvement. On MRI, the majority of information on the extent of the tumor, especially in terms of T1-weighted sequence (shows a hyperintense signal (restricted diffusion). A contrast-enhanced coronal C

tal lobe, mainly on the left. An axial diffusion-weighted imaging sequence (hyperintense signal (edema) can be seen in the brain parenchyma in the fron-
ted lesion presented an isointense signal, although a hyperintense signal (edema) can be seen in the brain parenchyma in the frontal lobe, mainly on the left. An axial diffusion-weighted imaging sequence (C) shows a hyperintense signal (restricted diffusion). A contrast-enhanced coronal T1-weighted sequence (D) shows intense enhancement.

A indicates that the tumor is limited to the nasal cavity; stage B indicates that it involves only the nasal cavity and paranasal sinuses; and stage C indicates that it extends beyond the stage B limits. The staging system proposed by Dulguerov employs the tumor-node-metastasis classification

Bone destruction and calcification within the lesion can be characterized by CT. An MRI scan provides more accurate information on the extent of the tumor, especially in terms of intracranial and orbital involvement. On MRI, the majority of olfactory neuroblastomas present a signal that is (in relation to that of muscle tissue) hypointense in T1-weighted sequences and hyperintense in T2-weighted sequences, as well as showing intense enhancement in contrast-enhanced sequences. MRI is also superior to CT in the evaluation of recurrence after craniofacial resection, because of its greater ability to differentiate fibrous scar tissue from residual or recurring neoplasia. Cysts in the intracranial margin of the tumor have been reported in cases of olfactory neuroblastoma. Another relevant aspect is a dumbbell-like morphology, the tumor mass being divided between the anterior cranial fossa and the nasal cavity, the cribriform plate forming the "waist".

The main differential diagnoses of olfactory neuroblastoma include: squamous cell carcinoma, typically in the maxillary antrum, with bone erosion; sinonasal adenocarcinoma, with heterogeneous enhancement, which has been associated with occupational exposure to wood dust; undifferentiated sinonasal carcinoma, which affects older patients; and dural-based invasive meningioma, with poorly defined borders and areas of necrosis.

Letters to the Editor

Giant ovarian teratoma: an important differential diagnosis of pelvic masses in children

Dear Editor,

An 8-year-old female patient presented with diffuse abdominal pain accompanied by progressive distension. Physical examination revealed a large abdominal mass, predominantly in the mesogastrium, that was compressible and painless on palpation. Ultrasound showed a solid-cystic formation extending from the epigastrum to the hypogastrium, with a calcium component and an air-fluid level (Figure 1). Computed tomography (CT) showed a massive solid-cystic formation, with a fat component and soft tissue, as well as calcifications, measuring 12.6 × 19.2 × 20.8 cm, exerting a significant mass effect, displacing the small intestine, aorta, and inferior vena cava, as well as causing slight compression of the pancreas, kidneys, and ureters, with no apparent signs of infiltration (Figure 2). Intraoperatively, the mass was seen to be adhered to the left fallopian tube and to the greater omentum (Figure 1). The tumor was excised without complications, and the patient was discharged five days later. A follow-up abdominal ultrasound revealed no changes.

The occurrence of an abdominal mass in a child should always be evaluated by a pediatrician. The main differential diagnoses are organomegaly and fecal impaction. When abdominal palpation produces nonspecific findings, further investigation, employing imaging methods, is required.
