Abstract
We study the distribution of the eigenvalues of the area operator in loop quantum gravity concentrating on the part of the spectrum relevant for isolated horizons. We first show that the approximations relying on integer partitions are not sufficient to obtain the asymptotic behaviour of the eigenvalue distribution for large areas. We then develop a method, based on Laplace transforms, that provides a very accurate solution to this problem. The representation that we get is valid for any area and can be used to study the asymptotics in the large area limit.

Keywords: area spectrum in loop quantum gravity, distribution of area eigenvalues, Hardy–Ramanujan formula

(Some figures may appear in colour only in the online journal)

1. Introduction

The problem of understanding the properties of the spectrum of the area operator in loop quantum gravity (LQG)—in particular the distribution of its eigenvalues—has been considered by a number of authors [1–4]. A motivation behind some of these works was to see if the old suggestion by Bekenstein and Mukhanov regarding the quantization of black hole areas [5–7] fitted within the context of LQG, where a rigorously defined area operator, with a discretized spectrum, was constructed [3]. The details of the spectrum for small areas, in
particular, the so called area gap (the value of the smallest non-zero eigenvalue), play an important role in physical applications of LQG ranging from black hole physics to quantum cosmology. This is so because it marks the scale at which quantum geometric phenomena play an important role (see, for example, the discussions in [8]). On the other hand, the behavior of the area spectrum for large areas must be relevant to understand the details of the semiclassical limit.

Of course, it is now well known that the distribution of the eigenvalues of the LQG area operator does not conform to the simple proposal of [5–7]. In fact, there is a widespread agreement on the exponential growth of their density as a function of the area [3, 9]. This is supported by evidence gleaned from the observed behaviour of the lowest part of the spectrum and plausibility arguments relying on classical results about integer partitions [2]. However, to our knowledge, there are no definitive quantitative results on this issue. The purpose of this paper is to fill this gap and discuss in some detail the methods that, in our opinion, are best suited to address this problem.

The full spectrum of the area operator $A_S$ associated with a surface $S$ is quite complicated (see [1, 3, 9]), however, when the graphs labeling quantum states have no edges lying within $S$ and gauge invariance is enforced, the eigenvalues of $A_S$ take the following simple form

$$A_S = 8\pi \gamma \ell_P^2 \sum_{i=1}^{n} \sqrt{j_i(j_i + 1)}, \quad j_i \in \frac{1}{2}\mathbb{N}, \quad n \in \mathbb{N},$$

(1.1)

where $\ell_P$ denotes that Planck length and $\gamma$ is the Immirzi parameter. A context where this particular expression plays an important role is in the modelling of quantum black holes with the help of isolated horizons [10, 11].

In the following we choose units such that $4\pi \gamma \ell_P^2 = 1$ and introduce positive integer labels $n_i = 2j_i$. By doing this, the last expression becomes

$$A_S = \sum_{i=1}^{n} \sqrt{n_i(n_i + 2)}, \quad n_i \in \mathbb{N}, \quad n \in \mathbb{N}.$$  

(1.2)

A natural way to study the distribution of the area eigenvalues consists in counting all the possible multisets of positive integers $n_i \in \mathbb{N}$ (maybe repeated) such that the sum in (1.2) is smaller or equal than a given value $a > 0$ (for concreteness the problem is precisely spelled out in the next section).

The main difficulty to solve this problem originates in the presence of the square root. A reasonable approach to gain some preliminary understanding on it is to consider approximations in which the square root is replaced by an integer (one expects them to be accurate if the numbers involved are large). The two most natural ones are $\sqrt{n_i(n_i + 2)} \sim (n_i + 1)$ and $\sqrt{n_i(n_i + 2)} \sim n_i$. Approximations of this type have been the starting point of the work discussed in several papers [2, 12]. When these simplifications are enforced, the spectrum becomes equally spaced and essentially corresponds to the one proposed by Bekenstein and Mukhanov.

For each area value $a$ let us call $N_-(a)$, $N(a)$ and $N_+(a)$ the number of different (unordered) choices of integers $n_i$ such that

$$\sum_i (n_i + 1) \leq a, \quad \sum_i \sqrt{n_i(n_i + 2)} \leq a, \quad \sum_i n_i \leq a,$$

respectively. As $n_i < \sqrt{n_i(n_i + 2)} < n_i + 1$ we immediately see that $N_-(a) \leq N(a) \leq N_+(a)$. A comparison between the two approximations and the exact values of $N(a)$ can be seen in
As it is apparent, $N^+(a)$ provides a very poor approximation for $N(a)$; it is not clear at all that the growth of $N(a)$ is captured by the one of $N^+(a)$. The behaviour of $N^-(a)$ is better but, even for the very restricted part of the spectrum shown in the figure, it is clear that $N^-(a)$ grows too slowly, raising again reasonable doubts about the possibility of capturing the behaviour of $N(a)$ with $N^-(a)$ in the large area limit.

The purpose of this paper is to analyze the behaviour of $N(a)$ and assess the validity of the approximations customarily used in this setting. We will not only manage to satisfactorily do so but, along the way, we will get very accurate formulas—valid for the whole range of areas—to count the number of eigenvalues as a function of the area $a$. From a physical perspective these formulas may be useful to study the semiclassical limit. The methods used here rely on well known results in analytic number theory and asymptotic analysis but introduce some novel elements. As we will justify in the paper, the standard techniques applied in the derivation of the Hardy–Ramanujan [13] and Rademacher [14] formulas (relevant in the analysis of the approximations mentioned above) cannot be directly generalized to the counting problem that we consider here. This is so because standard generating functions cannot be used in a straightforward way.

The layout of the paper is the following. After this introduction, we devote the very short section 2 to the precise statement of the counting problem that we solve. Section 3 describes the integer approximations mentioned above and some generalizations of them. We will show that it is not possible to get definitive conclusions from them about the true behaviour of the area spectrum (for instance for large areas). The main body of the paper is contained in section 4, where we study in detail the distribution of the eigenvalues of the area spectrum given by (1.2). We derive there a very good explicit formula that accounts for the behaviour of the whole area spectrum. We end with our conclusions and an appendix where we show how our methods can be used to study integer partitions and obtain asymptotic expansions of the Hardy–Ramanujan and Rademacher types.
2. Statement of the problem

For future reference and concreteness we state here the counting problem that we solve in the paper.

**Main Problem (MP).** For any given positive number $a > 0$ compute $N(a)$ defined as one plus the number of different multisets consisting of positive integers $n_i \in \mathbb{N}$ such that

$$\sum_i \sqrt{n_i(n_i+2)} \leq a.$$  \hspace{1cm} (2.1)

We add one for convenience (in any case, notice that zero is an eigenvalue of $\hat{A}_S$ associated with quantum geometry states labeled by graphs that do not intersect $S$). Notice that $N(a)$ is a staircase function.

An important comment is in order now: our purpose is to study the distribution of the area eigenvalues *without taking into account their multiplicities* (which are relevant, on the other hand, in black hole entropy computations [11, 15–17]). This notwithstanding, there is a ‘mild’ type of multiplicity (associated with what we call $j$-degeneracy) that we will allow. It corresponds to the possibility of having distinct multisets of integers $n_i$ giving the same value for the sum $\sum_i \sqrt{n_i(n_i+2)}$ (e.g. $\{6\}$ and $\{1,1,1,1\}$). Our choice is motivated by the fact that, on one hand, the set of degenerate eigenvalues in this sense appears to be small and, on the other, removing them complicates the computations without providing significant new insights into the problem.

3. Density of states for the integer approximations of the area spectrum

As we have mentioned in the introduction, a possible way to approach the study of the distribution of the area eigenvalues is to rely on integer approximations for the square root that appears in (1.2). We introduce now two auxiliary problems, based on approximations of this type, that we will briefly discuss in the following:

**Auxiliary Problem 1 (AP1).** For any given positive number $a > 0$ compute $N_-(a)$ defined as one plus the number of different multisets consisting of positive integers $n_i \in \mathbb{N}$ such that

$$\sum_i (n_i + 1) \leq a.$$  \hspace{1cm} (3.1)

**Auxiliary Problem 2 (AP2).** For any given positive number $a > 0$ compute $N_+(a)$ defined as one plus the number of different multisets consisting of positive integers $n_i \in \mathbb{N}$ such that

$$\sum_i n_i \leq a.$$  \hspace{1cm} (3.2)

Both can be conveniently rephrased in terms of integer partitions. AP1 is equivalent to computing

$$N_-(a) = 1 + \sum_{k \leq a} p_1(k) = 1 + \sum_{k=1}^{[a]} p_1(k),$$

where $p_1(k)$ is the number of partitions of $k$. AP2 is equivalent to computing

$$N_+(a) = 1 + \sum_{k \leq a} p_2(k) = 1 + \sum_{k=1}^{[a]} p_2(k),$$

where $p_2(k)$ is the number of partitions of $k$. These problems are the integer approximations of the area spectrum.
where \( p_1(k) \) denotes the number of partitions of \( k \) in terms of positive integers excluding 1. AP2 can be solved by computing

\[
N_+(a) = 1 + \sum_{k \leq a} p(k) = 1 + \sum_{k=1}^{|a|} p(k),
\]

where \( p(k) \) is the number of ordinary partitions of \( k \) in terms of positive integers.

A neat way to encode the solutions to the two preceding counting problems is through the use of generating functions. The generating functions for \( p_1(k) \) and \( p(k) \) are, respectively,

\[
f_-(z) := \sum_{k=0}^{\infty} p_1(k) z^k = \prod_{m=2}^{\infty} \frac{1}{1 - z^m}, \quad f_+(z) := \sum_{k=0}^{\infty} p(k) z^k = \prod_{m=1}^{\infty} \frac{1}{1 - z^m}. \tag{3.3}
\]

Notice that, by convention, we take \( p(0) = p_1(0) = 1 \).

For a given \( n \in \mathbb{N} \) the generating functions for \( N_-(n) \) and \( N_+(n) \) can be obtained from (3.3) by simply multiplying by \( 1/(1-z) = 1 + z + z^2 + z^3 + \cdots \). In fact, in order to solve AP1 we need to consider the generating function

\[
\frac{f_-(z)}{1-z},
\]

which is equal, actually, to the generating function for ordinary partitions \( f_+(z) \). This means that\(^5\)

\[
N_-(a) = [z^{|a|}] f_+(z) = p(\lfloor a \rfloor),
\]

(notice that this is the approximation employed in [2] although, in that paper, the authors take \( \sqrt{n_i(n_i+2)} \sim n_i \)).

An important classical result regarding the asymptotic approximation of \( p(n) \) was obtained by Hardy and Ramanujan (and later perfected by Rademacher) [13, 14] by using the so called circle method. Their formula provides and infinite number of terms for the asymptotic expansion of these numbers and allows one, in principle, to exactly compute them. For most practical purposes it suffices to consider the first term in their expansion. It is important to notice that the alternative forms of the asymptotic approximations to \( p(n) \) that appear in the literature differ significantly with regard to their accuracy for small values of \( n \) (hence, outside the asymptotic regime).

The simplest Hardy–Ramanujan formula gives

\[
N_-(a) \sim \frac{1}{4 \sqrt{3}} e^{\pi \sqrt{\frac{2a}{3}}}, \quad a \to +\infty. \tag{3.4}
\]

The asymptotic behaviour of \( N_+(a) \) can also be read from the Hardy–Ramanujan and Rademacher formulas. As an example of how the methods that we use in the paper work for these problems we derive it in appendix. The result is

\[
N_+(a) \sim \frac{1}{2 \pi \sqrt{2a}} e^{\pi \sqrt{\frac{2a}{3}}}, \quad a \to +\infty. \tag{3.5}
\]

\(^5\) We denote the coefficient of the \( z^n \) term in the Taylor expansion of a function \( f \) around \( z = 0 \) as \([z^n]f(z)\).
As we can see, these asymptotic behaviours are different, although they both share the exponential factor. The growth of $N_+(a)$ is indeed faster than that of $N_-(a)$ as the prefactors of the exponential term have different powers of $a$.

A possible improvement from the behaviour of $N_+(a)$ can be obtained by using the fact that $n < n + 1/2 < \sqrt{n(n+2)}$ for all $n \in \mathbb{N}$ and considering the following

**Auxiliary Problem 3 (AP3).** For any given positive number $a > 0$ compute $N_{1/2}(a)$ defined as one plus the number of different multisets consisting of positive integers $n_i \in \mathbb{N}$ such that

$$\sum \left(n_i + 1/2\right) \leq a.$$  \hspace{1cm} (3.6)

This condition is equivalent to

$$\sum_i (2n_i + 1) \leq 2a.$$  \hspace{1cm} (3.7)

If we define $p_{1\text{odd}}(n)$ as the number of partitions of a positive integer $n$ as sums of odd numbers excluding 1 we see that

$$N_{1/2}(a) = \sum_{k=0}^{[2a]} p_{1\text{odd}}(k).$$

The generating function for $p_{1\text{odd}}(n)$ is

$$f_{1/2}(z) := \sum_{k=0}^{\infty} p_{1\text{odd}}(k)z^k = \prod_{m=1}^{\infty} \frac{1}{1 - z^{2m+1}},$$  \hspace{1cm} (3.8)

and, hence, the generating function for $N_{1/2}(n)$ is

$$\frac{f_{1/2}(z)}{1 - z} = \prod_{m=0}^{\infty} \frac{1}{1 - z^{2m+1}} = \prod_{m=1}^{\infty} (1 + z^m),$$  \hspace{1cm} (3.9)

where the last equality is obtained by multiplying by 1 written in the form

$$\prod_{j=0}^{\infty} \frac{(1 - z^j)(1 + z^j)}{1 - z^j}$$

and cancelling equal terms in the numerator and the denominator. We conclude then that $N_{1/2}(n)$ can be interpreted as the number of partitions of $n$ into distinct summands. The asymptotic behaviour of these numbers is well known (see, for example, [18, p 580]) so we just borrow the result to get

$$N_{1/2}(a) \sim \frac{1}{4 \cdot 3^{1/4} (2a)^{3/4}} e^{\pi \sqrt{2a}}, \quad a \to +\infty.$$  \hspace{1cm} (3.10)

This growth is slower than that of $N_+(a)$ but faster than that of $N_-(a)$. As we can see we still get the same exponential factor as before. The interested reader can easily check that the inequality $n + r < \sqrt{n(n+2)}$ with $0 < r < 1$ (which is valid for large enough values of $n$) produces asymptotic approximations of the type (3.4), (3.5) and (3.10), with different prefactors of the exponential term.
After reaching this point, it seems justified to believe that the actual asymptotic behaviour of $N(a)$ involves $\exp(\pi \sqrt{\frac{2}{a}})$, but the other relevant factors cannot be guessed. Notice that, due precisely to the presence of the exponential term, the failure to pinpoint the exact nature of the prefactors implies that we can miss an exponentially large number of eigenvalues. In our opinion, it is not clear at all that the asymptotic behaviour of $N(a)$ can be determined by approximating $\sqrt{n(n+2)}$ in the ways explained above. A more effective approach is needed, we develop it in the next section.

4. Distribution of the eigenvalues of the area operator

A very convenient way to rephrase MP consists in determining the large $a$ behaviour of the staircase function $N(a)$ introduced in section 2. This type of function can be represented as an inverse Laplace transform (see [19] for details). To understand why this is so, notice that the standard Heaviside step function for $a > 0$ can be represented as

$$\theta(a-a_0) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} \frac{\theta(a-a_0)s}{s} ds,$$

with $c > 0$. This means that, if we can encode the jumps $\beta_n$ located at $a = a_n$ of a certain staircase function $N(a)$ in an expansion of the type

$$\hat{f}(s) = \sum_{n=0}^{\infty} \beta_n e^{-an}s,$$

we can, at least formally, write

$$N(a) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} \frac{\hat{f}(s)}{s} ds,$$

with the integration contour parallel to the imaginary axis and chosen in such a way that all the singularities of the integrand have real parts smaller than $c$.

For the AP1 of the preceding section we would have

$$\hat{f}_+(s) := f_+(e^{-s}) = \prod_{n=1}^{\infty} \frac{1}{1 - \exp(-ns)} = \exp \left( -\sum_{n=1}^{\infty} \log \left( 1 - e^{-ns} \right) \right).$$

In the case of MP it is straightforward to see that

$$\hat{f}(s) = \prod_{n=1}^{\infty} \frac{1}{1 - \exp (-s\sqrt{n(n+2)})} = \exp \left( -\sum_{n=1}^{\infty} \log \left( 1 - e^{-\sqrt{n(n+2)s}} \right) \right). \quad (4.1)$$

If the analytic structure of $\hat{f}(s)$ was simple (for instance, meromorphic or with just a finite number of branching points allowing it to be defined on a cut plane) it would suffice to compute residues at the poles of the integrand (or wrap the integration contour around the cuts) to get an asymptotic expansion for $N(a)$. However this is not true for (4.1) because $\hat{f}(s)$ cannot be analytically extended to the region $\Re(s) < 0$ so we need a different approach.

At the exact location of the jumps $a = a_n$ the integral gives just the arithmetic mean of the limits $\lim_{a \to a^+} N(a)$ and $\lim_{a \to a^-} N(a)$.
In the following we will use asymptotic methods relying on a saddle point approximation (in appendix we do this for the partition problem). To this end, it is necessary to get an appropriate representation for the function
\[
\phi(s) := -\sum_{n=1}^{\infty} \log \left( 1 - e^{-\sqrt{n(n+2)s}} \right)
\]
in the vicinity of the point \( s = 0 \). A very convenient one can be obtained by computing its Mellin transform and using the Mellin inversion formula (see [20]) to write
\[
\phi(s) = \frac{1}{2\pi i} \int_{-\hat{c}+i\infty}^{\hat{c}+i\infty} s^{-\hat{c}} \zeta'(t + 1) \Gamma(t) \sum_{n=1}^{\infty} \frac{1}{(n(n+2))^{y/2}} dt,
\]
(4.2)
with \( \hat{c} > 1 \). Although, in principle, the representation provided by (4.2) is only valid for \( s \in \mathbb{R} \) it can be extended for complex values of \( s \) by relying on the argument given in [18, p 576].

As we can see, the integrand in (4.2) consists of a number of pieces: the usual \( s^{-\hat{c}} \), two 'universal' factors \( \Gamma(t) \) and \( \zeta(t + 1) \) (compare with (A.4) in appendix), and the Dirichlet series (a generalized zeta function)
\[
\sum_{n=1}^{\infty} \frac{1}{(n(n+2))^{y/2}}.
\]
This last object can be extended to the complex plane as a meromorphic function \( \zeta_A(t) \) with an infinite number of isolated simple poles located at \( t = 1, -1, -3, -5, \ldots \). Indeed, by using the binomial series expansion in
\[
\sum_{n=1}^{\infty} \frac{1}{(n(n+2))^{y/2}} = \sum_{n=1}^{\infty} \frac{1}{(n+2)^{y/2}} \left( 1 - \frac{2}{n+2} \right)^{-1/2}
\]
we can write \( \zeta_A(t) \) in terms of Hurwitz zeta functions\(^7\) as
\[
\zeta_A(t) = \sum_{k=0}^{\infty} 2^k \frac{\Gamma(k+t/2)}{k! \Gamma(t/2)} \zeta(t + k, 3),
\]
and easily read its analytic properties, in particular the location of its poles.

With the help of this extension we can consider displacing the integration contour of (4.2) to the left and get the sought for representation of \( \phi(s) \) by computing the residues of
\[
F(s, t) := s^{-\hat{c}} \zeta'(t + 1) \Gamma(t) \zeta_A(t)
\]
at its poles \( t = +1, 0, -1, -2, -3, \ldots \). The representation that we are about to get is valid close to \( s = 0 \) which is precisely what we need to obtain the asymptotic behaviour of \( N(a) \) in the limit \( a \to +\infty \). The residues at these poles are

\(^7\) Remember that for \( z \) such that \( \text{Re}(z) > 0 \) and \( \text{Re}(\alpha) > 0 \) the Hurwitz zeta function is defined by the series
\[
\zeta(z, \alpha) = \sum_{n=0}^{\infty} (n + \alpha)^{-z}.
\]
\[ \text{Res}[F(s,t); t = +1] = \frac{\pi^2}{6s}, \]
\[ \text{Res}[F(s,t); t = 0] = \frac{3}{2} \log s - \log \sqrt{\pi}, \]
\[ \text{Res}[F(s,t); t = -1] = \frac{1}{4} s \log s - \alpha_s s, \]
\[ \text{Res}[F(s,t); t = -2m] = - \frac{\zeta(2m)}{2m} \left( \frac{s}{2\pi} \right)^{2m}, \quad m \in \mathbb{N}, \]
\[ \text{Res}[F(s,t); t = -2m - 1] = \sqrt{\pi} \zeta(2m + 1) \Gamma(m + 1/2) \left( \frac{s}{2\pi} \right)^{2m+1}, \quad m \in \mathbb{N}, \]

where the constant \( \alpha_s \) is given by the series
\[
\alpha_s := \frac{1}{6} + \frac{1}{4} \log(2\pi) + \frac{1}{4\sqrt{\pi}} \sum_{n=1}^{\infty} \frac{2^m}{n!} \Gamma(n - \frac{1}{2}) \zeta(n - 1, 3) 
\]
\[
= \frac{1}{6} + \frac{1}{4} \log(2\pi) + \frac{1}{2} \sum_{n=3}^{\infty} n \left( 1 - \frac{1}{n} - \frac{1}{2n^2} - \sqrt{1 - \frac{2}{n}} \right) \approx 0.765\,115\,321\,592 \cdots .
\]

The second expression for \( \alpha_s \) can be derived from the first by using the series definition for the \( \zeta \) function and exchanging the order of summation.

By adding the contribution of the \( t \)-residues of \( F(s,t) \) up to \( -(2M + 1) \) we obtain
\[
\hat{f}(s) = \frac{s^{3/2}}{\sqrt{\pi}} \exp \left( \frac{\pi^2}{6s} - \alpha_s s + \frac{1}{4} s \log s \right) 
\quad \cdot \exp \left[ \sum_{m=1}^{M} \left( - \frac{\zeta(2m)}{2m} \left( \frac{s}{2\pi} \right)^{2m} + \frac{\sqrt{\pi} \zeta(2m + 1) \Gamma(m + 1/2)}{(m + 1)!} \left( \frac{s}{2\pi} \right)^{2m+1} \right) \right] 
\quad \cdot \exp \left[ G_M(s) \right]. \tag{4.3}
\]

Notice that \( \hat{f}(s) \) is not exactly given by the terms appearing in the first two lines of (4.3) because of an extra contribution \( G_M(s) = \exp \left( O(s^M) \right) \) as \( s \to 0 \).

In the following it is convenient to consider the limit \( M \to \infty \) and write
\[
\hat{f}(s) = \frac{s^{3/2}}{\sqrt{\pi}} \exp \left( \frac{\pi^2}{6s} - \alpha_s s + \frac{1}{4} s \log s \right) F(s)G(s) \tag{4.4}
\]

where
\[
F(s) := \exp \left[ \sum_{m=1}^{\infty} \left( - \frac{\zeta(2m)}{2m} \left( \frac{s}{2\pi} \right)^{2m} + \frac{\sqrt{\pi} \zeta(2m + 1) \Gamma(m + 1/2)}{(m + 1)!} \left( \frac{s}{2\pi} \right)^{2m+1} \right) \right], \tag{4.5}
\]

and \( G(s) = \exp(O(s^M)) \) for every \( M \in \mathbb{N} \) [thus \( G(s) \) can be taken to be 1; notice, however, that it may play a relevant role if one wants to recover the full analytic structure of \( \hat{f}(s) \)].

The series appearing in (4.5) converges for \( |s| < 2\pi \). This is enough for our purposes, however it is interesting to point out that a nice analytic extension of it can be obtained by taking into account that...
\[
- \sum_{m=1}^{\infty} \frac{\zeta(2m)}{2^m} \left( \frac{s}{2\pi} \right)^{2m} = \frac{1}{2} \log \left( \frac{2}{s} \sin \frac{s}{2} \right),
\]

\[
\exp \left[ \frac{\sqrt{\pi}}{2} \sum_{m=1}^{\infty} \frac{\zeta(2m+1)\Gamma(m+1/2)}{(m+1)!} \left( \frac{s}{2\pi} \right)^{2m+1} \right] = \prod_{k=1}^{\infty} \exp \left[ -\frac{\pi^2 k}{s} \left( \sqrt{4 - \frac{s^2}{\pi^2 k^2}} - 2 + \frac{s^2}{4\pi^2 k^2} \right) \right],
\]

where, again, these expressions are obtained by using the series definition of the \( \zeta \) function and exchanging the order of summation. It should be pointed out that, for numerical evaluations, the product formula in the last equality is worse than the one involving the series (something analogous happens in the case of \( a_1 \)).

### 4.1. Computation of \( N(a) \): approximations and asymptotic analysis

Here we will concentrate on the computation of

\[
N(a) = \frac{1}{2\pi^{3/2} t^{1/2}} \int_{e^{-1/\alpha}}^{e^{+1/\alpha}} ds \left( a - a_* \right) s + \frac{\pi^2}{6s} + \frac{1}{4} s \log s \right) F(s) G(s) ds,
\]

(4.6)

where \( a_* \), \( F(s) \) and \( G(s) \) have been defined in the previous section. We will not content ourselves with an asymptotic approximation but will try to get a representation for \( N(a) \) valid for any value of the area \( a \). As we will see, the particular features of (4.6) will allow us to obtain a rather precise functional representation for it, in addition to a simple asymptotic expansion in the limit \( a \to +\infty \).

The first step in the determination of \( N(a) \) is to perform the change of variable \( s = \alpha t \) leading to

\[
N(a) = -\frac{1}{\alpha} \left( \frac{\alpha}{\pi} \right)^{3/2} \int_{e^{-1/\alpha}}^{e^{+1/\alpha}} t^{1/2} \exp \left( \alpha \left( a - a_* + \frac{1}{4} \log \alpha \right) t + \frac{\pi^2}{6\alpha t} + \frac{1}{4} t \log t \right) F(\alpha t) G(\alpha t) dt.
\]

(4.7)

By judiciously choosing \( \alpha \) we can write the exponential term as

\[
\exp \left( \frac{\pi^2}{6\alpha} t + \frac{1}{4} \log t \right).
\]

(4.8)

This expression is useful because the terms \( t^2 + 1/4t \) and \( t \log t \) both have a real stationary point at \( t = 1/e \). As we will see, this will help us find a very good approximation for \( N(a) \). Another reason why (4.8) is especially useful is the way the \( \alpha \)-dependent parameter \( \alpha \) appears: as \( 1/\alpha \) multiplying the first term and as \( \alpha \) multiplying the second.

The value of \( \alpha \) leading to (4.8) is

\[
\alpha = \exp \left( \frac{1}{2} W \left( \frac{4\pi^2 e^2}{3} e^{4(a-a_*)} \right) - 4(a-a_*) \right),
\]

(4.9)

where \( W \) is the Lambert function\(^8\). Remembering that \( W(x) \sim \log x - \log(\log x) \) as \( x \to +\infty \), it is straightforward to see that

\[
\alpha \sim \frac{\pi e}{\sqrt{6a}}, \quad a \to +\infty.
\]

\(^8\) The Lambert function is defined by the implicit equation \( W(z) \exp W(z) = z \).
This fact shows an additional advantage of the representation provided by (4.7): we can use \(1/\alpha\) as our asymptotic parameter instead of \(a\).

Let us look again at the exponential term (4.8). Owing to the fact mentioned above regarding the stationary points of \(e^{\alpha t} + 1/t\) and \(t \log t\), we can actually approximate \(t \log t\) in a neighborhood of \(t = 1/e\) as

\[
t \log t = -\frac{2}{e} + \frac{1}{2e^2} \left( e^{\alpha t} + \frac{1}{t} \right) + O \left( t - \frac{1}{e} \right)^3
\]

so that

\[
\exp \left( \frac{1}{4} \alpha t \log t \right) = \exp \left( -\frac{\alpha}{2e} \right) \cdot \exp \left( \frac{\alpha}{8e^2} \left( e^{\alpha t} + \frac{1}{t} \right) \right) \cdot \exp \left( O \left( t - \frac{1}{e} \right)^3 \right), \tag{4.10}
\]

and, hence, we can get a very good— but simple—approximation for (4.8):

\[
\exp \left( \frac{\pi^2}{6a} \left( e^{\alpha t} + \frac{1}{t} \right) + \frac{1}{4} \alpha t \log t \right) \sim \exp \left( -\frac{\alpha}{2e} \right) \cdot \exp \left( \frac{\alpha}{8e^2} + \frac{\pi^2}{6a} \right) \left( e^{\alpha t} + \frac{1}{t} \right). \tag{4.11}
\]

It is the particular form in which the integration variable \(t\) appears in the previous expression that will allow us to get a very accurate representation for \(N(a)\) in terms of modified spherical Bessel functions.

Finally, in a neighborhood of \(t = 1/e\), we write \(G(\alpha t)\) as 1 and \(F(\alpha t)\) as

\[
F(\alpha t) = F \left( \frac{\alpha}{e} \right) \left( 1 - \frac{1}{eH(\alpha)} \left( t - \frac{1}{e} \right) \right) + O \left( t - \frac{1}{e} \right)^2, \tag{4.12}
\]

where

\[
H(\alpha) = \sum_{m=1}^{\infty} \left( \zeta(2m) \left( \frac{\alpha}{2\pi e} \right)^{2m} - \sqrt{\pi} \frac{\zeta(2m + 1) \Gamma(m + 3/2)}{(m + 1)!} \left( \frac{\alpha}{2\pi e} \right)^{2m+1} \right). \tag{4.13}
\]

Plugging (4.10) and (4.12) into (4.7) it is possible to get successive approximations for \(N(a)\) by keeping terms up to a certain power of \(t - 1/e\). Here we will just consider the first two ones that we label as \(N_0\) and \(N_1\):

\[
N_0(a) = -\frac{i}{2} \left( \frac{\alpha}{\pi} \right)^{3/2} e^{-\frac{\pi}{2} F \left( \frac{\alpha}{e} \right)} \int_{\gamma - i\infty}^{\gamma + i\infty} r^{1/2} \exp \left( \left( \frac{\alpha}{8e^2} + \frac{\pi^2}{6a} \right) \left( e^{\alpha t} + \frac{1}{t} \right) \right) dr, \tag{4.14}
\]

\[
N_1(a) = -\frac{i}{2} \left( \frac{\alpha}{\pi} \right)^{3/2} e^{-\frac{\pi}{2} F \left( \frac{\alpha}{e} \right)} \left( 1 + H(\alpha) \right) \int_{\gamma - i\infty}^{\gamma + i\infty} r^{1/2} \exp \left( \left( \frac{\alpha}{8e^2} + \frac{\pi^2}{6a} \right) \left( e^{\alpha t} + \frac{1}{t} \right) \right) dr
+ \frac{i e}{2} \left( \frac{\alpha}{\pi} \right)^{3/2} e^{-\frac{\pi}{2} F \left( \frac{\alpha}{e} \right)} \left( 1 + H(\alpha) \right) \int_{\gamma - i\infty}^{\gamma + i\infty} r^{1/2} \exp \left( \left( \frac{\alpha}{8e^2} + \frac{\pi^2}{6a} \right) \left( e^{\alpha t} + \frac{1}{t} \right) \right) dr. \tag{4.15}
\]

A very nice, almost exact formula, for these expressions—our final trick—can be obtained by realizing that the exponent in the integrand is a characteristic feature of the contour integral representation of Bessel and modified Bessel functions. Indeed, by performing the change of variable \(\tau = et\) and changing the contour to a counterclockwise oriented circle \(C\) centered

\(^9\) Of course, it is possible to perform the two changes of variables that we use in this section in a single step by requiring the minimum of the exponent in (4.7) to be located at \(\tau = 1\). We have chosen a slightly longer presentation because it highlights the main ideas leading to the main result of the paper.
in the origin (which introduces only exponentially suppressed subdominant terms) we get the main result of our paper

\[ N_0(a) \sim -\frac{i}{2} \left( \frac{\alpha}{\pi \epsilon} \right)^{3/2} e^{-\frac{\alpha}{\epsilon}} F \left( \frac{\alpha}{\epsilon} \right) \int e^{\tau^{1/2}} \exp \left( \left( \frac{\alpha}{8 \epsilon} + \frac{\pi^2 \epsilon}{6 \alpha} \right) \left( \tau + \frac{1}{\tau} \right) \right) \, d\tau \]

\[ = \frac{e^{-\frac{\alpha}{\epsilon}}}{\sqrt{\pi}} \left( \frac{\alpha}{\epsilon} \right)^{3/2} F \left( \frac{\alpha}{\epsilon} \right) I_{-3/2} \left( \frac{\pi^2 \epsilon}{3 \alpha} + \frac{\alpha}{4 \epsilon} \right), \]

(4.16)

where \( I_{-3/2} \) is a modified Bessel function of the first kind

\[ I_{-3/2}(z) = \sqrt{\frac{2}{\pi z^{3/2}}} \left( z \sinh z - \cosh z \right). \]

In a similar fashion one finds

\[ \frac{1}{2} \]

\[ \frac{1}{3} \]

\[ \frac{1}{4} \]

\[ \frac{1}{5} \]

\[ \frac{1}{6} \]

\[ \frac{1}{7} \]

\[ \frac{1}{8} \]

\[ \frac{1}{9} \]

\[ \frac{1}{10} \]

**Table 1.** In this table we compare exact values of \( N(a) \) with the different approximations discussed in the text. We have rounded the values of all the approximations to the closest integer. As we can see, both \( N_0(a) \) and \( N_1(a) \) are quite accurate.

| \( a \) | \( N_0(a) \) | \( N_1(a) \) | \( N_1(a) \) |
|-----|-----|-----|-----|
| 10  | 68  | 42  | 42  |
| 20  | 979 | 678 | 679 |
| 30  | 8599 | 6282 | 6284 |
| 40  | 56682 | 42809 | 42817 |
| 50  | 307719 | 237955 | 237990 |
| 60  | 1448161 | 1140094 | 1140222 |
| 70  | 6099037 | 4870521 | 4870954 |

**Figure 2.** Comparison of the exact values of \( N(a) \) and the approximation \( N_0(a) \) given by (4.16) for the lowest lying part of the area spectrum. The plot obtained with the estimate (4.17) is essentially identical.
\[ N_1(a) \sim N_0(a) + \frac{e^{-\frac{\alpha}{e}}}{\sqrt{\pi}} \left( \frac{\alpha}{e} \right)^{3/2} F \left( \frac{\alpha}{e} \right) H(\alpha) \left( I_{-3/2} \left( \frac{\pi^2 e}{3 \alpha} + \frac{\alpha}{4e} \right) - I_{-5/2} \left( \frac{\pi^2 e}{3 \alpha} + \frac{\alpha}{4e} \right) \right) \]  

(4.17)

where

\[ I_{-5/2}(z) = \sqrt{\frac{\pi}{z^{5/2}}} \left( (3 + z^2) \cosh z - 3z \sinh z \right). \]

It is now straightforward to get from (4.16) an asymptotic expansion for \( N(a) \) in the limit \( a \to +\infty \)

\[ N(a) \sim \frac{1}{2\sqrt{6a}} e^{\pi \sqrt{\frac{2}{a}}} =: N_{as}(a). \]  

(4.18)

Although this expansion can obviously be obtained in a more direct way from (4.6) by using a saddle point approximation, we think that the possibility of finding a representation such as (4.16) has its merit, because it provides a very good approximation for low values of the area. We discuss this issue in the next section.

5. Checking the results: conclusions and comments

The purpose of this section is to assess the quality of the approximations furnished by (4.16) and (4.17) both at the asymptotic regime \( a \to +\infty \) and for small values of \( a \). We also want to check if the behaviour predicted by (4.18) is compatible with the one obtained from the approximations based on the partition problem, in particular \( N_0(a) \). This last question can be immediately answered: by comparing (4.18) and (3.4) we see that both expressions are proportional but not equal. The asymptotic approximation obtained from the partition problem and the Hardy–Ramanujan formula is smaller than (4.18) by a factor of \( \sqrt{2} \). This immediately explains the behaviour shown in figure 1. Although one can argue that both asymptotic behaviours are not dramatically different (their functional forms are essentially identical) it is important to realize that the difference between them grows exponentially.

Let us see now how (4.16) approximates the lowest part of the spectrum. To this end it suffices to plot \( N(a) \) and \( N_0(a) \) for small values of \( a \). The result can be seen in figure 2. The approximations obtained above are, obviously, very good. This is in marked contrast with the one provided by (4.18) which, as expected, does not work very well for small values of the area.

Extending the plot for a larger range of areas will wash out the details of the staircase function in such a way that the two curves would be essentially indistinguishable. However, it is interesting to thoroughly check the quality of our approximations for large areas. In order to find out how well (4.16) and (4.17), or (4.18) approximate \( N(a) \) it is necessary to obtain exact values for \( N(a) \). As \( N(a) \) grows very fast this can only be done, with modest computing means, for values of \( a \) of about several tens. In table 1 we give a sample of these results and compare them with the different approximations obtained in the paper.

As it can be seen, the approximations provided by \( N_0(a) \) and \( N_1(a) \) are increasingly good and the relative errors go to zero as the area grows (as expected). This is also true for \( N_{as}(a) \) although this can only be seen for very large areas\(^{10}\). This notwithstanding, it is important to point out that the difference between \( N(a) \) and \( N_0(a) \) (or \( N_1(a) \)) does not appear to go to zero.

\(^{10}\) A simple check of this fact consists in comparing the ratios of \( N_0(a) \) or \( N_1(a) \) with \( N_{as}(a) \) in the limit \( a \to \infty \).
A good idea of what is going on can be gleaned by plotting the difference of $N(a)$ and $N_0(a)$. Two such plots are shown in figures 3 and 4. As we can see, the envelope of the curve slowly increases with the area $a$. The plot with $N_1(a)$ looks essentially the same.

Figure 3. Plot of the difference $N(a) - N_0(a)$ evaluated only at the points of the area spectrum (we have joined the points in the plot to make it easier to understand). The exact value of $N(a)$ oscillates about the one given by $N_0(a)$. As we can see, the envelope of the curve slowly increases with the area $a$. The plot with $N_1(a)$ looks essentially the same.

Figure 4. Zoom of the previous plot for areas in the range $(20, 25)$. It is interesting to notice the almost periodicity of $N(a) - N_0(a)$ once the increasing amplitude is divided out. Taking into account that the value of $N(a)$ in this area range is between 682 and 2171, we see that the relative error is of around 1%. This relative error decreases with $a$.

as $a \to \infty$. A good idea of what is going on can be gleaned by plotting the difference of $N(a)$ and $N_0(a)$. Two such plots are shown in figures 3 and 4. As we can see, $N_0(a)$ oscillates around the exact value $N(a)$ in an almost periodic fashion (the same is true for $N_1(a)$). This behaviour can be explained by the analytic structure of $\hat{f}(s)$ defined in (4.1), in particular, by the periodic concentration of singularities around the values $s = 2k\pi i$ with $k \in \mathbb{Z}$. Although one can, in principle, use the methods that we have explained in the paper to explore these further
corrections to \(N_0(a)\) and \(N_1(a)\) and estimate their relative errors with respect to \(N(a)\), we think that the information that we have obtained gives a satisfactory answer to the questions that we posed at the beginning so we will stop our analysis here. The quality of our approximations hinges on the fact that the lack of periodicity of \(\phi(s)\) in the imaginary direction effectively makes the contributions of other saddle points negligible with respect to the one that we have used in the paper. As we will mention at the end of the appendix, this behaviour differs from the one of \(\phi_p(s)\), the analogous of \(\phi(s)\) for partitions.

The precise information that we have obtained regarding the behavior of the area spectrum in the large area limit should be important to address problems related to the semiclassical limit of LQG. Despite the fact that many computational details in the paper are tied to the concrete form of the area spectrum, we hope that the methods developed here may be useful to study the spectra of other geometric operators. This is an interesting line of work that we expect to pursue in the future.

Acknowledgments

This work has been supported by the Spanish MINECO research grants FIS2014-57387-C3-3-P and FIS2017-84440-C2-2-P. Juan Margalef-Bentabol is supported by ‘la Caixa’ and ‘Residencia de Estudiantes’ fellowships. One of the authors (JFBG) wants to thank Kirill Krasnov for a discussion that prompted the analysis of the different approximations based on the partition problem discussed in the paper. We also want to thank K Giesel, H Sahlmann, T Thiemann and the Quantum Gravity Group at the FAU University in Erlangen for interesting discussions and comments. Some of the computations and the plots have been done with the help of Mathematica™.

Appendix. Asymptotics of partitions via Laplace transforms

In this appendix we will obtain the asymptotics of \(p(n)\) leading to (3.4) and (3.5). Let us consider

\[
N_p(n) := \sum_{k=0}^{n} p(k),
\]

and its Laplace transform representation \((n > 0)\)

\[
N_p(n) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} \frac{e^{ns}}{s} \prod_{k=1}^{n} \frac{1}{1-e^{-ks}} \, ds. \tag{A.1}
\]

Defining now

\[
\phi_p(s) := -\sum_{n=1}^{\infty} \log(1 - e^{-ns}) \tag{A.2}
\]

and computing its Mellin transform

\[
M[\phi_p; t] = \zeta(t+1)\Gamma(t)\zeta(t), \tag{A.3}
\]

we get the following integral representation for \(\phi_p(s)\)

\[
\phi_p(s) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} s^{-t}\zeta(t+1)\Gamma(t)\zeta(t) \, dt. \tag{A.4}
\]
The integrand has simple poles at $t = +1$ and $t = -1$ and a double pole at $t = 0$. By computing the residues at them we get

$$\exp \phi_p(s) = \sqrt{\frac{s}{2\pi}} \exp \left( \frac{\pi^2}{6s} - \frac{s}{24} \right) \cdot G_p(s), \quad (A.5)$$

where the explicit form of $G_p(s)$ is irrelevant because $G_p(s) = \exp(O(s^M))$ for all $M$ as $s \to 0$. We hence conclude

$$N_p(n) = \frac{1}{(2\pi)^{1/2}i} \int_{c-i\infty}^{c+i\infty} s^{-1/2} \exp \left( \left(n - \frac{1}{24}\right)s + \frac{\pi^2}{6s} \right) G_p(s) ds. \quad (A.6)$$

By performing now the change of variable $s = \beta_n t$ in such a way that the real stationary point of the exponential is at $t = 1$ we get

$$N_p(n) = \frac{\beta_n^{1/2}}{(2\pi)^{1/2}i} \int_{c-i\infty}^{c+i\infty} t^{-1/2} \exp \left( \frac{\pi^2}{6\beta_n} \left(t + \frac{1}{1}\right) \right) G_p(\beta_n t) dt, \quad (A.7)$$

with

$$\beta_n = \frac{\pi}{\sqrt{6 \left(n - \frac{1}{24}\right)}}.$$ 

By proceeding as in section 4.1 we get the approximation

$$N_p(n) \sim \frac{1}{\sqrt{24n - 1}} \left( \frac{\pi}{6} \sqrt{24n - 1} \right), \quad (A.8)$$

leading to the asymptotic behaviour (3.5). The asymptotics of $p(n)$ can be immediately obtained by differentiating the preceding expression (or (3.5)) with respect to $n$. Equation (A.8) is essentially equivalent to the first term in the convergent Rademacher expansion. It is interesting to point out that (A.2) is periodic in the imaginary direction. It is possible then to compute the contribution of the saddle points obtained by translating the one considered here in steps of $2k\pi i$. Although these are suppressed with respect to this one owing to the $1/s$ factor in (A.1) they will give an oscillating correction contributing to the staircase shape of $N_p(n)$.
