ABSTRACT

Context. Studying molecular gas in the central regions of the star burst galaxies NGC 4945 and Circinus enables us to characterize the physical conditions and compare them to previous local and high-z studies.

Aims. We estimate temperature, molecular density and column densities of CO and atomic carbon. Using model predictions we give a range of estimated CO abundance ratios.

Methods. Using the new NANTEN2 4 m sub-millimeter telescope in Pampa La Bola, Chile, we observed for the first time CO 4–3 and [CI] 1–0 at the centers of both galaxies at linear scale of 682 pc and 732 pc respectively. We compute the cooling curves of 12CO and 13CO using radiative transfer models and estimate the physical conditions of CO and [CI].

Results. The centers of NGC 4945 and Circinus are very [CI] bright objects, exhibiting [CI] 13P1−3P0 luminosities of 91 and 67 K km s−1 kpc−2, respectively. The [CI] 13P0−3P1/2,3/2 CO 4–3 ratio of integrated intensities are large at 1.2 in NGC 4945 and 2.8 in Circinus. Combining previous CO J = 1–0, 2–1 and 3–2 and 13CO J = 1–0, 2–1 studies with our new observations, the radiative transfer calculations give a range of densities, n(H2) = 103−3 × 104 cm−3, and a wide range of kinetic temperatures, Tkin = 20−100 K, depending on the density. To discuss the degeneracy in density and temperature, we study two representative solutions. In both the galaxies estimated total [CI] cooling intensity is stronger by factors of ≃1–3 compared to the total CO cooling intensity. The CO/C abundance ratios are 0.2–2, similar to values found in Galactic translucent clouds.

Conclusions. Our new observations enable us to further constrain the excitation conditions and estimate the line emission of higher-J CO and the upper [CI] lines. For the first time we give estimates for the CO/C abundance ratio in the center regions of these galaxies. Future CO J = 7–6 and [CI] 2–1 observations will be important to resolve the ambiguity in the physical conditions and confirm the model predictions.

1. Introduction

The spiral galaxies NGC 4945 and Circinus at distances of ≃3.7 and ≃4 Mpc belong to the nearest and infrared brightest galaxies in the sky. Their strong central star burst activity is fed by large amounts of molecular material and this has been studied extensively at millimeter wavelengths (e.g. Curran et al. 2001a; Wang et al. 2004). However, sub-millimeter observations are largely missing. The important rotational transitions of CO with J ≥ 4 and the fine structure transitions of atomic carbon have not yet been observed. These transitions often contribute significantly to the thermal budget of the interstellar gas in galactic nuclei and are therefore important tracers of the physical conditions of the warm and dense gas.

Emission of CO, [C I] (and [C II]) traces the bulk of carbon bearing species in molecular clouds that play an important role in their chemical network. The CO 4–3 transition in particular is a sensitive diagnostic of the dense and warm gas while the CO 1–0 transition traces the total molecular mass. The [C I] 3P1−3P0 (henceforth 1–0) line has, to date, been detected in about 30 galactic nuclei (Gerin & Phillips 2000; Israel & Baas 2002; Israel 2005) and appears to trace the surface regions of clumps illuminated by the FUV field of newborn, massive stars (e.g. Kramer et al. 2004, 2005). The use of CI as an accurate tracer of the cloud mass has been discussed with controversy (Frerking et al. 1989; Papadopoulos & Greve 2004; Mookerjea et al. 2006).

The strong cooling emission is balanced by equally strong heating caused by the vigorous star formation activity in the galaxy centers. The variation of CO cooling intensities with rotational number, i.e. the peak of the CO cooling curve, reflects the star forming activity (Bayet et al. 2006) and, possibly, also the underlying heating mechanisms. Several mechanisms have been proposed to explain the heating of the ISM in galactic nuclei and it is currently rather unclear which of these dominates in individual sources (e.g. Wang et al. 2004). Heating by X-rays from the active galactic nuclei (AGN) may lead to strongly
enhanced intensities of high-J CO transitions (Meijerink et al. 2007), possibly allowing one to discriminate this heating mechanism from e.g. stellar ultraviolet heating via photon dominated regions (PDRs) (e.g. Bayet et al. 2006). The greatly enhanced supernova rate by several orders of magnitude relative to the solar system value leads to an enhanced cosmic ray flux, providing another source of gas heating in the centers (Farquhar et al. 1994; Bradford et al. 2003). Another mechanism for heating is provided by shocks. The most important, large-scale shocks are produced by density instability waves which induce gravitational torques (in spiral arms and/or bars) and make the gas fall into the nucleus (Usero et al. 2006). A non-negligible contribution is also given by shocks produced by supernova explosions. On smaller scales, bipolar outflows from young stellar objects (YSO) can also contribute to this heating, although to a lesser extent (e.g. García-Burillo et al. 2001).

1.1. NGC 4945

NGC 4945, a member of the Centaurus group of galaxies, is seen nearly edge-on (Table 1) with an optical diameter of ~20′′ (de Vaucouleurs et al. 1991). H1 kinematics indicate a galaxy mass of 1.4 × 10^{11} M_☉ within a radius of 6.3′ with molecular and neutral atomic gas contributing ~2% respectively (Ott et al. 2001).

With a dynamical mass of ~3 × 10^{9} M_☉ in the central 600 pc (Mauersberger et al. 1996), it is one of the strongest IRAS point sources with almost all the far infrared luminosity coming from the nucleus (Brock et al. 1988). Observations of the X-ray spectrum are consistent with a Seyfert nucleus (Iwasawa et al. 1993), and further analysis of optical imaging and infrared spectra (Moorwood & Oliva 1994) suggests that this object is in a late stage on the transition from starburst to a Seyfert galaxy. Its nucleus was the first source in which a powerful H2O mega maser was detected (Dos Santos & Lépine 1979).

Studies in H1 (Ables et al. 1987) and low-J CO transitions (Whiteoak et al. 1990; Dahlem et al. 1993; Ott 1995; Mauersberger et al. 1996) suggest the presence of a face-on circumnuclear molecular ring. Millimeter molecular multiple transition studies (Wang et al. 2004; Cunningham & Whiteoak 2005) are consistent with this result. The bright infrared and radio emission in the nucleus (Ghosh et al. 1992), and the evidence that large amounts of gas seem to coexist in the central 30′′ (Henkel et al. 1994) make it particularly suited for studying the high density environment in the center of this galaxy.

1.2. Circinus

The nearby starburst spiral Circinus has a small optical angular diameter of ~7′′ compared to its hydrogen diameter D_H = 36′ defined by the 1 × 10^{20} atoms cm⁻² contour in Freeman et al. (1977).

Circinus has a dynamical mass of ~3 × 10^{9} M_☉ within the inner 560 pc (Curran et al. 1998) matching the value obtained for NGC 4945. Large amounts of molecular gas have been found by studies of low-J CO observations (Johansson et al. 1991; Aalto et al. 1995; Elmouttie et al. 1998; Curran et al. 1998) including C^{15}O, C^{18}O and HCN (Curran et al. 2001a). The strong H2O maser emission found (Gardner & Whiteoak 1982) traces an thin accretion disk of 0.8 pc radius, with a significant population of masers lying away from this disk, possibly in an outflow (Greenhill et al. 1998). Its obscured nucleus is classified as an X-ray Compton thick Seyfert 2. It shows a circumnuclear star burst on scales of 100–200 pc (Maiolino et al. 1998) with a complex structure of H II as seen in Hubble Space Telescope (HST) Hα images (Wilson et al. 2000). Adaptive optics studies find there has been a recent star burst (~100 Myr old) in the central 8 pc accounting for 2% of the total luminosity (Mueller Sánchez et al. 2006). The strong FIR emission, the large molecular gas reservoir, the existence of a molecular ring associated with star burst activity (Curran et al. 1998) and the similarity with NGC 4945 make them ideal objects for comparative studies of the dense and warm ISM in their nuclei.

### Table 1. Basic properties of Circinus, NGC 4945 and NGC 253

|          | Circinus | NGC 4945 | NGC 253 |
|----------|----------|----------|---------|
| RA(2000) | 14:13:09.9 | 13:05:27.4 | 00:47:33.1 |
| Dec(2000) | -65:20:21 | -49:28:05 | -25:17:18 |
| Type      | SA(s)b      | SB(s)cd     | SAB(s)       |
| Distance [Mpc] | 4.0th | 3.7th | 3.5th |
| 38° correspond to | 732 pc | 682 pc | 646 pc |
| LSR velocity [km s⁻¹] | 434 | 555 | 243 |
| Inclination [deg] | 65° | 78° | 78° |
| L_{HI} [10^{10} L_{☉}] | 1.41th | 1.39th | 2.67th |
| δ sin[deg] | 3.16 × 10^2 | 6.86 × 10^2 | 10.4 × 10^2 |

L_{IR} is the total mid and far infrared luminosity calculated from the flux densities at 12 µm, 25 µm, 60 µm, 100 µm which are consistent with this result. The bright infrared and radio emission in the nucleus (Brock et al. 1988). Observations of the dense and warm ISM in their nuclei. The relative calibration uncertainty derived from repeated pointings on the nuclei is about 15%.

Position-switching was conducted by moving the telescope 10′′ in azimuth, i.e. out of the galaxy. Using double beam-switch (dbS) mode, the chopper throw is fixed at 162′′ in azimuth with a chopping frequency of 1 Hz. Typical double-sideband receiver temperatures of the dual-channel 460/810 GHz receiver were ~250 K at 460 GHz and 492 GHz. The system temperature varied between ~850 and ~1200 K. As backends we used two casse dol optical spectrometers (AOS) with a bandwidth of 1 GHz and a channel resolution of 0.37 km s⁻¹ at 460 GHz and 0.21 km s⁻¹ at 806 GHz. The pointing was regularly checked and pointing accuracy was stable with corrections of ~10′′.

We used the new NANTEN2 sub-millimeter telescope (e.g. Kramer et al. 2007) on Pampa la Bola at an elevation of 4900 m together with a dual channel 490/810 GHz receiver (operated jointly by the Nagoya University radioastronomy group and the KOSMA group from Universität zu Köln) to observe the centers of NGC 4945, Circinus, and NGC 253 (Table 1) in CO 4–3 and [CI] 1–0. The observations were performed from September to October 2006 using the position-switch mode with 20′′ On and 20′′ Off-time. In October 2007 we reobserved 12CO 4–3 in the centers of NGC4945 and Circinus with the newly available chopping tertiary in double beam-switch mode yielding significantly improved baselines and removing atmospheric features in the spectra. In NGC 4945 the total integration times ON-source are 17 min and 10 min for 12CO 4–3 and [CI] 1–0 respectively and in Circinus integration times ON-source are 10 min and 34 min for 12CO 4–3 and [CI] 1–0 respectively at source elevations of 40–60°. The relative calibration uncertainty derived from repeated pointings on the nuclei is about 15%.
half power beam width (HPBW) at 460 GHz and 492 GHz is 38′′ with a beam efficiency $B_{\text{eff}} = 0.50$ and a forward efficiency $F_{\text{eff}} = 0.86$ (Simon et al. 2007). The calibrated data on $T_A^*-$scale were converted to $T_{\text{mb}}$ by multiplying by the ratio $F_{\text{eff}}/B_{\text{eff}}$. The standard calibration procedure derives the atmospheric transmission (averaged over the bandpass) from the observed difference spectrum of hot load and blank sky, the latter taken at a reference position. Next, the model atmosphere atm is used to derive the atmospheric opacity taking into account the sideband imbalance. This is an important correction, especially when observing the CO 4–3 and [C\textsc{i}] 1–0 lines. This pipeline produces the standard spectra on the antenna temperature scale ($T_A^*$). In addition, we removed baselines up to first order.

The 810GHz channel was not used for these observations due to insufficient baseline stability.

All data presented in this paper are on the $T_{\text{mb}}$ scale.

### 2.1. $^{12}$CO 4–3 in NGC 253

To check the NANTEN2 calibration scheme, we retrieved the $^{12}$CO 4–3 map of NGC 253 taken at APEX (Güsten et al. 2006) and smoothed it to the NANTEN2 HPBW of 38′′ using a Gaussian kernel. The resulting spectra at the center position are shown in Fig. 1. Line temperatures and shapes show very good agreement.

### 3. Spectra of CO 4–3 and [C\textsc{i}] 1–0

Figure 2 shows the $^{12}$CO 4–3 and [C\textsc{i}] 1–0 spectra of NGC 4945 and Circinus obtained with the NANTEN2 telescope. CO 4–3 spectra peak at 700 mK in NGC 4945 and 250 mK in Circinus. Outside the velocity ranges of 350–800 km s$^{-1}$ and 200–600 km s$^{-1}$ respectively, the baseline rms values are 11 mK and 25 mK, respectively, at the velocity resolution of 15 km s$^{-1}$. [C\textsc{i}] 1–0 spectra peak at 900 mK in both galaxies while the rms values are 110 mK and 140 mK, respectively. The [C\textsc{i}] 1–0 area-integrated luminosities are 91 K km s$^{-1}$ pc$^2$ and 67 K km s$^{-1}$ pc$^2$ in NGC 4945 and Circinus.

Curran et al. (2001a, 1998) and Mauersberger et al. (1996) mapped the low-J 2–1, and 3–2 transitions of CO in the centers of both galaxies with SEST. We smoothed these data to the resolution of the NANTEN2 data, i.e. to 38′′. Only the $^{12}$CO 3–2 spectrum in Circinus is shown at its original resolution of 15′′ because a map of the central region could not be retrieved. Calibration of the CO 3–2 spectrum in NGC 4945 was confirmed recently at APEX (Risacher et al. 2006). The $^{12}$CO 1–0, $^{13}$CO 1–0 and $^{13}$CO 2–1 spectra of the central region of NGC 4945 and Circinus are presented in Curran et al. (2001a). We list integrated intensities in Table 2.

NGC 4945 shows broad emission between 350 and 800 km s$^{-1}$. The CO 4–3 line shape resembles the line shapes of 1–0 and 2–1. The line shape of [C\textsc{i}] 1–0 is similar to that of the CO transitions with a slightly higher peak temperature than CO 4–3.

In CO 1–0 and 2–1, Circinus shows broad emission between 200 and about 600 km s$^{-1}$. The velocity component at $\sim550$ km s$^{-1}$ becomes weaker with rising rotational number. Emission of [C\textsc{i}] 1–0 is restricted to 200 and $\sim500$ km s$^{-1}$ only. In Circinus, the [C\textsc{i}] peak temperature is a factor $\sim3$ stronger than CO 4–3.

### 4. Physical conditions

#### 4.1. LTE

In the optically thin limit, the integrated intensities of [C\textsc{i}] and $^{13}$CO listed in Table 2 are proportional to the total column densities. LTE column densities of carbon are rather
independent of the assumed excitation temperatures (e.g. Frerking et al. 1989). We find $N_C = 3.4-3.9 \times 10^{10}$ cm$^{-2}$ in NGC 4945 and $N_C = 2.2-2.5 \times 10^{18}$ cm$^{-2}$ in Circinus for a temperature range of $T_{ex} = 20-150$ K.

We used the $^{13}$CO $J = 1-0$ and $J = 2-1$ integrated intensities to derive total CO column densities, assuming LTE, optically thin $^{13}$CO emission, a CO/12CO abundance ratio of 40 (Curran et al. 2001a), and $T_{ex} = 20$ K. We find a total CO column density of $N_{CO} = 1.0-1.7 \times 10^{18}$ cm$^{-2}$ and $N_{CO} = 4.1-6.7 \times 10^{17}$ cm$^{-2}$ in NGC 4945 and Circinus respectively depending on which transition is used, 1–0 or 2–1. Varying the temperature to a range of $T_{kin} = 20-180$ K with higher temperature solutions corresponding to lower densities. The best fitting solution $T$ which transition is used, 1–0 or 2–1. Varying the temperature to a range of $T_{kin} = 20-180$ K with higher temperature solutions corresponding to lower densities. The best fitting solution

Another method uses the Galactic CO $1–0$ to H$_2$ conversion factor $X_{MW} = 2.3 \times 10^{20}$ cm$^{-2}$ (K km s$^{-1}$)$^{-1}$ (Strong et al. 1988; Strong & Mattio 1996) and the canonical CO to H$_2$ abundance of 8.5 $\times 10^{-5}$ (Ferkin et al. 1982) to derive $N_{CO} = 3.5 \times 10^{18}$ cm$^{-2}$ for Circinus, i.e. a factor of $\sim 10$ larger than the LTE estimate indicating that the X-factor is only 1/10 Galactic. As the abundance of CO maybe different in NGC 4945 and Circinus this result has to be taken with caution.

For NGC 4945 Wang et al. (2004) derive an X-factor 7 times smaller than the Galactic value, which leads to $N_{CO} = 1.4 \times 10^{18}$ cm$^{-2}$, in good agreement with the LTE approximation from $^{13}$CO. The LTE column density derived from $^{13}$CO in Circinus also indicates an X-factor around 10 times smaller than the Galactic value.

The CO/C abundance ratio is 0.29–0.50 in NGC 4945 and 0.19–0.27 in Circinus using the LTE column densities.

### 4.2. Radiative transfer analysis of CO and $^{13}$CO

We modeled the $^{12}$CO and $^{13}$CO emission lines using an escape probability radiative transfer model for spherical clumps (Stutzki & Winnewisser 1985) using the CO collision rates of Shinke et al. (1985). This non-LTE model assumes a uniform density and temperature in a homogenous clump. The physical parameters kinetic temperature $T_{kin}$, molecular density $n$(H$_2$), and column density $N_{CO}$ determine the excitation conditions in this model (Table 3).

For NGC 4945 and Circinus, we used the ratios of the observed integrated intensities of CO $1–0$ to $4–3$ and the $^{13}$CO $1–0$ and $2–1$ transitions (Curran et al. 2001a) to obtain column densities, density and kinetic temperature, assuming a constant $^{12}$CO/$^{13}$CO abundance ratio. We used an abundance ratio of 40 in both sources in accordance with Curran et al. (2001a).

The escape probability code uses an internal clump line width $\Delta v_{mod}$ of an individual clump to the beam width of the galaxy spectrum $\Delta v_{obs}$ and the beam dilution, due to the size of the modeled clump $A_k$ compared to the beam area $A_{beam}$.

The large velocity width of the observed spectra implies several clumps in the beam $N_{cl} = n \Delta v_{obs}/\Delta v_{mod}$ with $n \geq 1$ in NGC 4945 (Table 3). The beam dilution is determined by the fraction of modeled clump area to the beam size which we express in terms of an area filling factor per clump $\phi_{A} = A_{k}/A_{beam}$. The total area filling factor is $\phi_{A} = N_{cl} \phi_{A,cl}$. The size of the clump with radius $R$, $\phi_{A} = n R$, can be inferred via the mass $M$ and density $n$(H$_2$) of the clump: $R = (3/(4\pi)mn)^{1/3}$. In summary, the modeled densities of the individual clumps $n_{mod}$ are converted to the intensities of a clump ensemble $I_{mod}$ which can then be compared with the observed intensities:

$$I_{obs} = I_{mod} \times N_{cl} \times \phi_{A,cl} = I_{mod} \times \phi_{A}$$

Table 3. Escape probability model results with two representative solutions for each source.

| Source      | $T_{kin}$ [K] | $n$(H$_2$)$_{loc}$ [cm$^{-3}$] | $N_{CO}$ [10$^{16}$ cm$^{-2}$] | $N_{12CO}$ [10$^{16}$ cm$^{-2}$] | $N_{13CO}$ [10$^{15}$ cm$^{-2}$] | $T_{mod}$ [K] | $N_{mod}$ [10$^{16}$ cm$^{-2}$] | $M_{mod}$ [10$^6$ $M_\odot$] | $\Delta v_{mod}$ [km s$^{-1}$] | $\Delta v_{obs}$ [km s$^{-1}$] | $\phi_{A}$ |
|-------------|---------------|---------------------------------|---------------------------------|---------------------------------|---------------------------------|---------------|---------------------------------|-----------------------------|-----------------------------|-----------------------------|----------|
| Circinus    | 200           | 50.0                            | 180                             | 150                             | 120                             | 20            | 100                             | 5.0                         | 5.0                         | 5.0                         | 0.5      |
| NGC 4945    | 100           | 10.0                            | 100                             | 100                             | 100                             | 100           | 100                             | 100                         | 100                         | 100                         | 0.25     |

In Circinus the $^{12}$CO $3–2$ line is missing, leaving one degree of freedom compared to two in NGC 4945.

$T_{kin}$ and $n$(H$_2$) are determined with this step. To compare the modeled integrated intensities $I_{mod}$ to the absolute observed intensities $I_{obs}$, we have to account for the velocity filling, due to the velocity width $\Delta v_{mod}$ of an individual clump to the width of the galaxy spectrum $\Delta v_{obs}$ and the beam dilution, due to the size of the modeled clump $A_{k}$ compared to the beam area $A_{beam}$.

The large velocity width of the observed spectra implies several clumps in the beam $N_{cl} = n \Delta v_{obs}/\Delta v_{mod}$ with $n \geq 1$ in NGC 4945 (Table 3). The beam dilution is determined by the fraction of modeled clump area to the beam size which we express in terms of an area filling factor per clump $\phi_{A} = A_{k}/A_{beam}$. The total area filling factor is $\phi_{A} = N_{cl} \phi_{A,cl}$. The size of the clump with radius $R$, $\phi_{A} = n R$, can be inferred via the mass $M$ and density $n$(H$_2$) of the clump: $R = (3/(4\pi)mn)^{1/3}$. In summary, the modeled densities of the individual clumps $n_{mod}$ are converted to the intensities of a clump ensemble $I_{mod}$ which can then be compared with the observed intensities:

$$I_{obs} = I_{mod} \times N_{cl} \times \phi_{A,cl} = I_{mod} \times \phi_{A}$$

#### 4.2.1. NGC 4945

Figure 3b shows the observed intensities of CO, $^{13}$CO, and [C I] together with two representative solutions of the radiative transfer calculations (see also Table 3).

CO. Fitting the CO and $^{13}$CO lines, we find a degeneracy in the $n$(H$_2$) $\times$ $T_{kin}$ plane of the solutions for a rather constant pressure $n$(H$_2$) $\times$ $T_{kin}$ $\sim$ 10$^5$ K cm$^{-3}$. The best fits are achieved for a $^{12}$CO/$^{13}$CO abundance ratio of 40, similar to the value found by Curran et al. (2001a). Low $\chi^2$-values (see Table 3) constrain the densities to $n$(H$_2$) $\sim$ 10$^5$-10$^5$ cm$^{-3}$ and temperatures to a wide range of $T_{kin} = 20–180$ K with higher temperature solutions corresponding to lower densities. The best fitting solution...
Fig. 3. Radiative transfer modeling results and observations: filled blue points show the observed CO and blue circles the modeled CO. The dotted line indicates the best fit solution. Filled red triangles show the observed 13CO and red triangles the modeled 12CO. Dash-dotted lines show a higher temperature solution. Filled black points are the observed [CI] integrated intensities and black circles the predicted [CI] integrated intensities. Assumptions of optically thin emission in the LTE might be overestimated for the latter solution is a factor of 2.

The fitted column density \( N_{\text{CO}} \) agrees with the LTE approximation for the CO-column density within a factor of 2–3.

The peak of the modeled CO cooling curve at \( J = 4 \) contains 35.6% of the total 12CO cooling intensity of 6.6 \( \times 10^{-5} \) erg s\(^{-1}\) cm\(^{-2}\) sr\(^{-1}\) computed by summing the cooling intensity of the 12CO transitions from \( J = 1 \) to 20 for the \( T_{\text{kin}} = 20 \) K solution.

We use the radiative transfer model to predict the 12CO 7–6 intensity. It is rather weak, depending strongly on \( T_{\text{kin}} \). It varies from 1.3 K km s\(^{-1}\) for the \( T_{\text{kin}} = 20 \) K solution to 4.1 K km s\(^{-1}\) for the \( T_{\text{kin}} = 100 \) K.

Curran et al. (2001a) find in this source \( n(\text{H}_2) = 3 \times 10^3 \) cm\(^{-3}\) and \( T_{\text{kin}} = 100 \) K from 12CO observations of the 3 lowest transitions and 13CO data of the two lowest transitions. In their multi-transition study Wang et al. (2004) estimate a density of \( n(\text{H}_2) = 10^4 \) cm\(^{-3}\) for an assumed temperature \( T_{\text{kin}} = 50 \) K from CO transitions up to \( J = 3 \). In contrast, the observed CN and CH\(_2\)OH lines indicate local densities around \( 10^4 \) cm\(^{-3}\). The solutions for CO and 13CO found in the literature are in good agreement with our parameter space of solutions showing that the additional CO 4–3 line does not help significantly to improve the fits.

Atomic carbon. Assuming the same density, kinetic temperature, velocity filling, and beam dilution for carbon as for CO, we use the observed [CI] intensity and the radiative transfer model to estimate the carbon column density and hence the CO/C abundance ratio. The CO/C abundance ratio varies between 0.23 and 0.64 for the two solutions listed in Table 3. The corresponding carbon column densities are \( N_C = 3.3 \times 10^{18} \) cm\(^{-2}\) and \( N_C = 9.8 \times 10^{17} \) cm\(^{-2}\) for the high and the low density solution, respectively. The column density for the latter solution is a factor of 3 lower compared to the LTE carbon density. The assumption of optically thin emission in the LTE might be overestimating the column density compared to the escape probability modelling. We also use the model to predict the [CI] 2–1 intensity. It is 16 K km s\(^{-1}\) for the \( T_{\text{kin}} = 20 \) K/n(\text{H}_2) = 3 \( \times 10^4 \) cm\(^{-3}\) solution. However, this result critically depends on the kinetic temperature. The \( T_{\text{kin}} = 100 \) K/n(\text{H}_2) = 10^4 \) cm\(^{-3}\) solution yields 182 K km s\(^{-1}\). Also, the [CI] 2–1/[CI] 1–0 line ratios change from 0.07 to 0.75, depending on the solution. This shows that the high-lying transitions can be used to break the degeneracy.

The total cooling intensity of both [CI] lines is listed in Table 3 for both presented solutions. The cooling intensity of the two [CI] lines is thus of the order of the total cooling intensity of CO with the C/CO cooling intensity ratio varying between 1.1–2.1 for the discussed solutions.

4.2.2. Circinus

CO. The modeled CO cooling curves are shown in Fig. 3a and the fit results are summarized in Table 3. The CO line ratios are given for a \( \Delta v_{\text{mod}} = 5 \) km s\(^{-1}\) and there are about 40 clouds in the beam to account for the observed velocity width of \( \Delta v_{\text{obs}} = 186 \) km s\(^{-1}\). The assumed 12CO/13CO abundance ratio of 40 is slightly lower than the values of ~60, found by Curran et al. (2001a).

Good fits corresponding to low \( \chi^2 \) (see Table 3) can be found for densities of \( n(\text{H}_2) = 10^4 \) cm\(^{-3}\), \( T_{\text{kin}} = 20 \) K and a column density of \( N_{\text{CO}} = 3.5 \times 10^{17} \) cm\(^{-2}\) assuming 50 modeled clumps in the beam. The column density \( N_{\text{CO}} \) is well determined showing a steep gradient of \( \chi^2 \)-values for varying densities and temperatures. This is in reasonable agreement with the LTE-approximation from 13CO. A second solution at \( n = 10^3 \) cm\(^{-3}\) and \( T_{\text{kin}} = 100 \) K also lies within the 1\( \sigma \)-contour of the \( \chi^2 \) distribution (cf. Fig. 3 and Table 3).

The results agree well with the solutions found by Curran et al. (2001a). They find \( T_{\text{kin}} = 50–80 \) K and \( n(\text{H}_2) = 2 \times 10^4 \) cm\(^{-3}\) from observations of the 3 lowest 12CO transitions and the 2 lowest 13CO transitions.

The modeled CO cooling curve peaks at \( J = 4 \) containing 35% of the total 12CO cooling intensity of 2.1 \( \times 10^{-5} \) erg s\(^{-1}\) cm\(^{-2}\) sr\(^{-1}\) for the \( T_{\text{kin}} = 20 \) K fit.

The predicted integrated intensity of 12CO 7–6 is very weak, varying strongly from 0.1 K km s\(^{-1}\) for the \( T_{\text{kin}} = 20 \) K solution to 1.9 K km s\(^{-1}\) for \( T_{\text{kin}} = 100 \) K.

Atomic carbon. Assuming the same density and temperature for carbon as for CO, we use the best fitting CO model to derive the [CI] 1–0 intensity, carbon column densities, and CO/C abundance ratios. The predicted CO/C abundance ratio is 0.15, again consistent with the optically thin LTE result. The predicted [CI] 2–1 integrated intensity is 6.1 K km s\(^{-1}\).

As in NGC 4945, changing the temperature has a large effect on the [CI] 2–1 intensity. The \( T_{\text{kin}} = 100 \) K solution yields 111 K km s\(^{-1}\) and a higher CO/C abundance ratio of 1.67. Thus the [CI] 2–1/[CI] 1–0 line ratios changes from 0.04 to 0.74.

The corresponding carbon column densities for the two presented solutions are \( N_C = 2.3 \times 10^{18} \) cm\(^{-2}\) and \( N_C = 3.0 \times 10^{17} \) cm\(^{-2}\), respectively. For the latter solution the column density is about a factor of 10 lower compared to the LTE carbon column density. The optically thin assumption for the LTE modelling is obviously not appropriate in the high temperature and low density scenario.
The total cooling intensity ratio of [C I]/CO varies from 2.1 to 2.8 for the presented solutions. Carbon is a stronger coolant than CO by a factor of 2–3.

5. Discussion

5.1. [C I] 1–0 luminosities

The [C I] 1–0 luminosities for the centers of the Seyfert galaxies NGC 4945 and Circinus are 91 and 67 K km s\(^{-1}\) kpc\(^2\) (Fig. 4). To date, about 30 galactic nuclei have been studied in the 1–0 line of atomic carbon, most of which are presented in Gerin & Phillips (2000) and Israel & Baas (2002). The [C I] luminosity of a source is an important property since it gives the amount of energy emitted per time which is proportional to the number of emitting atoms, i.e. proportional to the [C I] column density in the limit of optically thin emission. The NANTEN2 380\(^\circ\) beam achieves ~700 pc resolution in Circinus and NGC 4945 which both lie at ~4 Mpc. To achieve the same spatial resolution for galaxies at ~12 Mpc distance, e.g. for NGC 278, NGC 660, NGC 1068, NGC 3079 and NGC 7331 listed in Israel & Baas (2002), one would need an angular resolution of ~13\(^\prime\), comparable to the 10\(^\prime\) JCMT beam at 492 GHz. The luminosities studied in these 7 sources thus all sample the innermost ~700 pc. Area integrated [C I] luminosities are found to vary strongly between ~1 and ~160 K km s\(^{-1}\) kpc\(^2\) in these 7 galaxies (Fig. 4) (Israel 2005; Israel & Baas 2002). Quiescent centers show modest luminosities 1 ≤ \(L([\text{C} \text{ I}])\) ≤ 5 K km s\(^{-1}\) kpc\(^2\), while starburst nuclei in general show higher luminosities. The largest luminosities are found in the active nuclei of NGC 1068 and NGC 3079 which show 50 and 160 K km s\(^{-1}\) kpc\(^2\) (Israel & Baas 2002). NGC 4945 and Circinus also fall in this category (Fig. 4).

5.2. [C I] 1–0/CO 4–3 line ratios

The [C I] 1–0/CO 4–3 ratio of integrated intensities is 1.2 in NGC 4945 and 2.8 in Circinus. For Circinus the ratio is larger than any ratios previously observed in other galactic nuclei or in the Milky Way. The [C I]1–0/CO 4–3 ratio is shown in Fig. 4 versus the area integrated [C I] luminosity. As also discussed in Israel & Baas (2002), we see no functional dependence. Galactically sources (not shown in this figure) would lie in the lower left corner. Israel (2005) studied 13 galactic nuclei and found that the [C I] 1–0 line is in general weaker than the CO 4–3 line, but not by much. Ratios vary over one order of magnitude between 0.1 in Maffei2 and 1.2 NGC 4826. Galactic star forming regions like W3 Main or the Carina clouds show much lower values, between about 0.1 and 0.5, which are consistent with emission from photon dominated regions (PDRs) (Kramer et al. 2004; Jakob et al. 2007; Kramer et al. 2007). Fixsen et al. (1999) find 0.22 in the Galactic center and 0.31 in the Inner Galaxy. The variation seen in the various Galactic and extragalactic sources appears to be intrinsic and not due to observations of different angular resolutions. This is because the frequencies of the two lines are very close and angular resolutions are therefore similar if the same telescope is used.

5.3. [C I] 1–0/\(^{13}\)CO 2–1 line ratios

The [C I] 1–0/\(^{13}\)CO 2–1 line ratios in NGC 4945 and Circinus are 5.51 and 8.57, respectively (Fig. 4). In NGC 4945, the observed ratio is consistent with results found in previous studies (Israel & Baas 2002; Gerin & Phillips 2000) ranging up to ratios of 5. For Circinus, the ratio is again higher than any previous measurement.

Two thirds of the sample of galaxies studied by Israel & Baas (2002) show [C I] 1–0/\(^{13}\)CO 2–1 line ratios well above unity. The sample consists of quiescent, star burst and active nuclei. The highest [C I] 1–0/\(^{13}\)CO 2–1 ratios are found in star burst and active nuclei, consistent with our observations. Gerin & Phillips (2000) find a similar result with two thirds of the galaxies in their sample exceeding a ratio of 2. High ratios can be qualitatively understood in low column density environments with mild UV radiation fields. In these regimes most CO will be dissociated and the gas-phase carbon will be neutral atomic (Israel & Baas 2002). This implies that dense, star forming molecular cloud cores are not the major emission source in galaxy centers.

In general the studied centers of external galaxies show stronger [C I] emission than one would expect from Galactic observations, which show typical ratios of 0.2–1.1 (Mookerjea et al. 2006). In Galactic sources high ratios are found in low gas column densities and medium UV radiation environments where \(^{13}\)CO will be dissociated and atomic carbon remains neutral in the gas phase i.e. in translucent clouds and at cloud edges (Israel 2005). He concludes that the dominant emission from galaxy centers does not stem from PDRs.

Meijerink et al. (2007) studied irradiated dense gas in galaxy nuclei using a grid of XDR and PDR models. For the same density the predicted [C I] 1–0/\(^{13}\)CO 2–1 line ratios are significantly higher for the XDR- compared to PDR-models (Fig. 10 in Meijerink et al. 2007). We observed ratios of 61 and 95 in NGC 4945 and Circinus respectively, on the erg-scale. These ratios can be explained by XDR-models at high densities \(n(H_2) = 2 \times 10^3–10^5 \text{ cm}^{-3}\). PDR-models explain the observed ratios in low density regimes with \(n(H_2) = 2 \times 10^2–6 \times 10^3 \text{ cm}^{-3}\). The high [C I] 1–0/\(^{13}\)CO 2–1 line ratios observed in NGC 4945 and Circinus may hint at a significant role of X-ray heating in these galaxy nuclei as our predicted densities of \(n(H_2) = 10^3–10^4 \text{ cm}^{-3}\) agree with the high-density XDR-models in Meijerink et al. (2007).

5.4. Total CO and [C I] cooling intensity

In all sources studied by Bayet et al. (2006) but NGC 6946, the CO cooling intensity exceeds that of atomic carbon. They find the [C I] to CO cooling ratio to vary between ~0.3 for M83 to ~2 for NGC 6946. NGC 4945 and Circinus show similarly high...
values as the latter galaxy: in NGC 4945 this ratio is $\sim 1$–2 and in Circinus we find $\sim 2$–3. These values are around 2 orders of magnitude higher than the typical values found in Galactic star forming regions (Jakob et al. 2007; Kramer et al. 2007).

5.5. Shape of the CO cooling curve

The modeled CO cooling curve of NGC 4945 and Circinus peaks at $J = 4$. Observations of the higher lying CO lines i.e. the CO 6–5 and CO 7–6 lines will however be important to verify our model predictions and the importance of CO cooling relative to C.

The shape and maximum of the cooling curve of $^{12}\text{CO}$ has been studied in a number of nearby and high-z galaxies. Fixsen et al. (1999) find a peak at $J = 5$ in the central part of the Milky Way using FIRAS/COBDE data and rotational transitions up to 8–7. Bayet et al. (2006) observed 13 nuclei in mid-J CO lines up to 7–6 and find that the peak of the cooling curves vary with nuclear activity. While normal nuclei exhibit peaks near $J_{\text{max}} = 4$ or 5, active nuclei show a peak near $J_{\text{max}} = 6$ or 7. NGC 253 was observed at APEX in CO up to $J_{\text{max}} = 7$ and shows a maximum at $J = 6$ (Güsten et al. 2006). On the other hand, studies of high redshift galaxies show cooling curves peaking as low as $J = 4$ for SMM 16353 (Weiß et al. 2005), as high as $J = 9$ in the case of the QSO APM 08279 (Weiss et al. 2007), and peaking at $J = 7$ for the very high redshift ($z = 6.4$) QSO J11148 (Walter et al. 2003).

5.6. Pressure of the molecular gas

A wide range of temperatures $T_{\text{kin}} = 25$–150 K and densities $n(H_2) = 5 \times 10^2$–7 $\times 10^4$ cm$^{-3}$ has been found in similar studies of external nuclei, including ULIRGs, normal spirals, star burst galaxies, and interacting galaxies (e.g. Bayet et al. 2006; Israel & Baas 2002). In the irregular galaxy IC 10 rather high densities ($n(H_2) \sim 10^4$ cm$^{-3}$) and low temperatures of $T_{\text{kin}} = 25$ K are found while the molecular gas in the center of the spiral galaxy NGC 6946 is found to be less dense, $n(H_2) \sim 10^3$ cm$^{-3}$, but much hotter, $T_{\text{kin}} = 130$ K. Güsten et al. (2006) studied NGC 253 to obtain $n(H_2) = 10^{3.9}$ cm$^{-3}$ and $T_{\text{kin}} = 60$ K while Bradford et al. (2003) investigated the same source and derived a higher $T_{\text{kin}} = 120$ K and density $n(H_2) = 4.5 \times 10^3$ cm$^{-3}$. Both studies used 12 CO 7–6 observations. However, the temperature/density degeneracy cannot be resolved. The solutions we present in our model predictions and the importance of CO cooling relative to C.

5.7. [C I] 2–1/1–0 line ratio

The modeled [C I] 2–1/1–0 line ratios change from 0.07 to 0.75 in NGC 4945 and from 0.04 to 0.74 in Circinus for the presented escape probability solutions. Observed ratios vary from 0.48 in G333.0-0.4 (Tieftrunk et al. 2001) to 2.9 in W3 main for galactic and extragalactic sources (Kramer et al. 2004). For M82, Stutzki et al. (1998) found a ratio of 0.96. Bayet et al. (2006) observed ratios ranging between 1.2 (in NGC 253) to 3.2 (in IC 342). The [C I] 2–1/1–0 line ratio for the low temperature solution predicted for NGC 4945 and Circinus is significantly lower than previous results in the literature.

5.8. CO/C abundance ratio

Compared to an abundance ratio CO/C of 3–5 in NGC 253 (Bayet et al. 2004) and an average value of 2 in the nucleus of M83 (White et al. 1994; Israel & Baas 2001), NGC 4945 and Circinus have a higher fraction of atomic carbon in their nuclei which resembles the low CO/C abundance ratios found in Galactic translucent clouds. We find values of 0.23–0.64 in NGC 4945 and 0.15–1.67 in Circinus. Due to the degeneracy of $n(H_2)$ T the abundance ratios cannot be determined more accurately. In galactic molecular clouds values range between 0.16–100, low values are found in translucent clouds (Stark & van Dishoeck 1994) while massive star forming regions show high CO/C abundances (Mookerjea et al. 2006).

5.9. Future observations

Future observations of CO 7–6 and [C I] 2–1 will be important to better understand the the kinetic temperature and density to resolve their degeneracy, and for an understanding of the dominating heating mechanism i.e. X-ray or UV heating. We estimate detection of the [C I] 2–1 line with NANTEN2 within less than 10 min total observation time under average weather conditions. The CO 7–6 will be harder to detect, depending on the excitation conditions. At 810 GHz the 1 GHz bandwidth of the receiver translates into a velocity range of 370 km s$^{-1}$. We therefore plan to stack future observations to be able to cover the broad line widths of Circinus and NGC 4945.

Acknowledgements. We thank S.Curran for providing us with the SEST-data for Circinus, R. Mauersberger and G. Rydberg for SEST-data for NGC 4945, and R. Güsten and S. Philipp for the APEX-data of NGC 253. The NANTEN2 project (southern submillimeter observatory consisting of a 4-m telescope) is based on a mutual agreement between Nagoya University and The University of Chile and includes member universities from six countries, Australia, Republic of Chile, Federal Republic of Germany, Japan, Republic of Korea, and Swiss Confederation. We acknowledge that this project could be realized by financial contributions of many Japanese donators and companies. This work is financially supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology of Japan (No.15071203) and from JSPS (No. 14102003 and No.18684003), and by the JSPS core-to-core program (No.17004). This work is also financially supported in part by the grant SFB 494 of the Deutsche Forschungsgemeinschaft, the Ministerium für Innovation, Wissenschaft, Forschung und Technologie des Landes Nordrhein-Westfalen and through special grants of the Universität zu Köln and Universität Bonn. L.B. and J.M. acknowledge support from the Chilean Center for Astrophysics FONDAP 15010003.
