St. Luke’s Medical Center, Quezon City, Philippines

ABSTRACT

Central neurocytomas are rare intraventricular tumors of neuronal origin that most commonly affect young adults. These tumors have a benign course and excellent prognosis after surgery. We present the first documented case of an 18-year-old healthy Filipino male presenting with new-onset generalized seizures and a heterogeneously enhancing left lateral ventricle tumor on imaging. The tumor was completely excised through endoscopic surgery, after which the patient made a complete recovery. Proper selection of cases, coupled with neurosurgeon expertise, solidifies endoscopic surgery as a safe and reasonable approach to achieve gross total resection of an intraventricular tumor.

Introduction

Central neurocytomas are uncommon tumors, accounting for less than 1% of all primary brain tumors [1-3]. The rarity of this tumor has impeded standardization of treatment. Prognosis is excellent after gross surgical resection, hence most studies recommend surgery as the primary modality [2-11]. Choosing the endoscopic approach over open surgery is dependent on tumor location and size [10, 12-14]. Most central neurocytomas are intraventricular, making total resection challenging. Neuroendoscopy may be employed to gain access to these deep-seated tumors. Tumors that are ideal for total endoscopic resection are singular lesions with soft consistency, small diameter (<2cm), mild-to-moderate vascularity, low histological grade and a completely intraventricular location accessible through a straight trajectory [10, 12]. Enlarged ventricles confer the advantage of a larger working space. In small or normal-sized ventricles, endoscopic surgery should be attempted only if the surgeon has substantial experience and proficiency [13]. For these cases, neuronavigation increases the accuracy of selecting an entry site [15]. The total endoscopic resection of an intraventricular central neurocytoma has not been reported in the Philippines and only a few cases have been documented in published studies [12-15]. A systematic literature review was performed using PubMed and Herdin (from 1980-2020). Search terms included central neurocytoma, neuroendoscopy, endoscopy, endoscopic surgery, excision and intraventricular tumors.

Case Presentation

This is a case of an 18 year-old Filipino right-handed male with no history of epilepsy or childhood illnesses presenting with new-onset generalized tonic-clonic seizures triggered by strenuous activity, straining and lack of sleep. There were no headaches, vomiting episodes, behavioural or memory disturbances. On physical examination, he had intact memory, unremarkable fundoscopy and no focal neurologic deficits. An electroencephalogram showed frontal epileptiform discharges. Magnetic resonance imaging revealed a lobulated T1-hypointense, T2-hyperintense, faintly enhancing tumor located on the medial wall of frontal horn of the left lateral ventricle, obstructing the foramen of Monro. The tumor measured 1.5x0.9x0.9 cm (APxTxCC) (Figure 1).
Gross Total Endoscopic Resection of a Left Lateral Ventricle Central Neurocytoma in an 18-Year-Old Filipino Male: A Case Report

Our patient underwent gross total endoscopic resection of the left lateral ventricle tumor. The goals of the surgery were to relieve cerebrospinal fluid pathway obstruction, obtain a histopathologic diagnosis and accomplish maximal safe resection. The patient was positioned supine with head elevated at 30 degrees and neck at neutral position. The hair on the left side of the head was clipped. The head was then secured with a three-point fixation system. The left Kocher’s point located 3 cm lateral to the midline and 2 cm anterior to the coronal suture along the left midpupillary line was identified. Planned incision was plotted with a surgical marker. Registration with image-guidance system was conducted to plan the ideal trajectory to the ventricle (Figure 2).

After the optimal point of entry was established, the operative field was sterilized with 95% ethyl alcohol. A relaxed L-shaped incision was created on the left frontal area. The scalp flap was retracted anterolaterally. A frontal precoronal Burr hole followed by a cruciate durotomy large enough to accommodate the caliber of a rigid neuroendoscope (Aesculap® MINOP 0-degree ventricular endoscope) were created. The cortical entry point was located on the left middle frontal gyrus. The pia mater was coagulated and incised. Through an anterior transcortical approach, the ventriculostomy catheter was inserted 5 cm from the outer table of the calvarium, leading to the egress of clear cerebrospinal fluid. The catheter was rotated clockwise as it was being withdrawn to increase the caliber of the corticectomy. The rigid neuroendoscope was traversed through this corridor. Upon entry to the ventricle, the left thalamostriate vein, septal vein, choroid plexus leading to the foramen of Monro and the septum pellucidum were identified to establish orientation. The grayish-white, dome-shaped, smooth-walled, broad-based tumor arising from the septum pellucidum was seen obstructing the foramen of Monro (Figure 3). The neuroendoscope was advanced to the base of the tumor to delineate the tumor-ependyma interface.

The tumor had a soft, feathery consistency and was excised in piecemeal fashion using biopsy forceps. Gross total excision of the tumor was performed. The tumor bed was coagulated after complete excision of the mass. No intraventricular hemorrhage was encountered. Cerebrospinal fluid egressed to the foramen of Monro. Continuous irrigation with warm lactated Ringer's solution for 15 minutes ensured hemostasis. Final inspection confirmed that the vasculature and surrounding structures were intact. A French 8 feeding tube was inserted 5 cm into the ventricle, anchored to the scalp using silk sutures and connected to an external drainage bag. Closure of the scalp was done. The total operative time was 3 hours. The external ventricular drain was removed on the 2nd post-operative day and the patient was discharged on the 5th post-operative day. Histopathologic studies and immunostaining confirmed the diagnosis of central neurocytoma, WHO Grade II (Figure 4). Repeat imaging done two weeks after surgery showed non-demonstration of the intraventricular mass and confirmed gross total resection (Figure 1). The patient was followed-up every 3 months and has been asymptomatic with no seizure recurrences. Postoperative radiation or chemotherapy was not pursued.
endoscopic excision is attainable with low risk of morbidity. In this case, the tumor was soft, feathery, and easily grasped by biopsy forceps. Hemorrhage was not encountered due to cautious resection and continuous irrigation. Relief of CSF pathway obstruction was accomplished at the end of surgery. The patient had an unremarkable post-operative course and became seizure-free, demonstrating that neuroendoscopy is a safe and feasible approach to the total excision of an intraventricular central neurocytoma. Appropriate patient selection, neuronavigation and neurosurgeon expertise are essential to improve patient outcome and mitigate the risk of neurologic complications.
