Field emission from metallic tips with nanometer sharpness has been introduced some time ago as a highly bright and coherent electron source. Only recently, pulsed electron sources with high spatiotemporal resolution were realized by laser-induced field emission from such tips. Potentially, spatiotemporal resolution down to the single atom and the attosecond range appears to be possible. Such electron sources would be very attractive for applications in time-resolved electron microscopy or scanning probe microscopy. However, the interaction of the laser pulses with the sharp tip and the electron emission mechanism are not yet fully understood.

When a focused laser pulse illuminates the tip, optical electric fields are modified at the tip apex due to the excitation of surface electromagnetic (EM) waves that couple with collective surface charge excitations to form, e.g., surface plasmon polaritons. Interference effects of the resulting surface EM waves can lead to local-field enhancement. Depending on the field strength, different electron emission processes become dominant. For relatively weak fields, single electron excitations by single-photon or multiphoton absorption are dominant, and photoexcited electrons are tunneling through the surface potential barrier; such processes are termed photofield emission. On the other hand, very strong local fields largely modify the tunneling barrier and prompt the field emission directly, leading to optical field emission. So far, the different emission processes were disputed in the literature, while the local-field enhancement was treated as a static effect such as the lightening rod effect. Hence, local fields on the tip apex are considered to be symmetric with respect to the tip axis. However, when the tip size is larger than approximately a quarter wavelength, dynamical effects are predicted to occur.

Here, we used a tip whose apex was approximately a quarter wavelength and we investigated laser-induced field-emission patterns. We have found that dynamical effects substantially influence the symmetries of local-field distributions and thereby field-emission intensity distributions. Varying the following three parameters changes these distributions substantially: (1) the laser polarization, (2) the azimuthal, and (3) the polar orientation of tip apex relative to the laser incidence direction. These are effects that had not been observed in earlier experiments. At the same time, we realized an ultrafast pulsed field-emission source with emission site selectivity on the scale of a few tens of nanometers. In our previous paper, simulations confirm that the photofield-emission process is dominant in laser-induced field emission. Here, we further discuss electron emission processes and their dependence on laser power and tip voltage by investigating electron emission patterns, Fowler-Nordheim (FN) plots, and calculated electron energy distributions. At relatively low laser power and high tip voltage, field emission after two-photon photoexcitation is the dominant process. At still relatively low laser power and low tip voltage, multiphoton photoemission over the surface barrier is dominant. As laser power increases, photoemission from the tip shank contributes.

This paper consists of four main sections. In Sec. II, we explain our experimental setup and our theoretical model. In Sec. III, we discuss the optical control of field-emission sites and the emission mechanism based on simulations of local fields on the tip apex and laser-induced field-emission microscopy (LFEM) images. In Sec. IV, we discuss the emission processes for varying laser power and tip voltage based on experimental and calculated results. In the last section, we present conclusions and proposals for future experiments.

II. METHODOLOGY

A. Experimental setup

Figure 1(a) schematically illustrates our experimental setup. A tungsten tip is mounted inside a vacuum chamber...
direction. A position-sensitive detector with a Chevron-apex being crystallized and oriented toward the talline tungsten, heating to around 2500 °C leads to the tip being approximately 4 \( \mu \)m (1/e\(^2\) radius) measured by a method with a razor blade. Linearly polarized laser light was used. The polarization vector can be changed within the transversal \((x,z)\) plane by using a \( \lambda/2 \) plate. As shown in the inset, the laser propagates toward the reader’s eye as denoted by the circled dot, the polarization angle \( \theta_p \) is defined by the angle between the tip axis and the polarization vector.

The tip can be heated to clean the apex and also negatively biased for field emission. Although the tip apex is polycrystalline tungsten, heating to around 2500 °C leads to the tip apex being crystallized and oriented toward the (011) direction. A position-sensitive detector with a Chevron-type double-channel-plate amplifier in front of the tip is used to record the emission patterns. The spatial resolution of field-emission microscopy (FEM) is approximately 3 nm.4

The tip holder can move along three linear axes \((x,y,z)\) and has two rotational axes for azimuthal \((\varphi,\text{around the tip axis})\) and polar \((\theta,\text{around the z axis})\) angles.24 The laser propagates parallel to the horizontal \( y \) axis within an error of \( \pm 1^\circ \). \( \theta \) is set so that the tip axis is orthogonal to the laser propagation axis. The orthogonal angle in \( \theta \) was determined by plotting positions of the tip in \((x,y)\) coordinates while keeping the tip apex in the focus of the laser as schematically shown in Fig. 1(b). The maximum position in \( x \) gives the orthogonal angle. Experimental data are shown in Fig. 1(c). The plots were taken in 0.5° steps. The data clearly show the maximum in the \( x \) position. We defined the corresponding angle as \( \theta = 0 \) for convenience. The precision is estimated to be \( \pm 1^\circ \). In these experiments, the base line of the rectangular detector is approximately 20° off from the horizontal \((y\) axis) incidence direction, which means that the laser propagation axis is inclined by 20° from the horizontal line in the observed laser-induced FEM images [see dashed red arrow in Fig. 3(a)]. All the measurements were done at room temperature.

### B. Theoretical model

Although the field emission is a quantum-mechanical phenomenon, the interaction between the optical fields and the tungsten tip apex can be treated classically by solving the Maxwell equations. Such an interaction can be understood by a mechanistic picture as shown in Fig. 2(a). When a laser pulse illuminates the metallic tip, surface EM waves are excited, which propagate around the tip apex. As a result of the interference among the excited waves, the optical fields are modulated. To simulate the superposition of surface EM waves and the resulting local-field distributions on the tip apex, we used the multiple multipole program (MMP), which is a highly accurate semianalytical Maxwell solver, available in the package MaxX, which is now also available as an open source project under the name OpenMaxX.

A droplet-like shape was employed as a model tip as shown in Fig. 2(b), with a radius of curvature of the tip apex of 100 nm, which is a typical value for a clean tungsten tip. Atomic structures were not included in the model because the tip apex can be regarded as a smooth surface on this length scale given by the tip dimensions and the wavelength of the laser field. The dielectric function \( \varepsilon \) of tungsten at 800 nm was used, i.e., a real part \( \text{Re}(\varepsilon) = 5.2 \) and an imaginary part \( \text{Im}(\varepsilon) = 19.4 \). Note that accuracy of the dielectric functions does not affect our conclusion, which will be demonstrated in Sec. III B by comparing with local fields on a gold tip. A focused laser with a beam waist of 1 \( \mu \)m (Ref. 29) and a wavelength of 800 nm was used as shown in Fig. 2(c). The model tip was set so that its apex is at the center of the focus.

By using different droplet sizes it was verified that the model tip is long enough so as to mimic the infinite length of the real tip; the fields at the truncated side of the tip are substantially weaker, so that the excited surface EM waves propagating around the whole tip do not affect the induced field distribution at the tip apex. Figure 2(d) shows the calculated time-averaged field distribution around the model tip in Fig. 2(b). Figure 2(e) shows the same calculated field dis-

---

**FIG. 1.** (Color online) Schematic of the experimental setup (a). A tungsten tip is mounted inside a vacuum chamber. Laser pulses are generated outside the vacuum chamber. An aspherical lens is located just next to the tip to focus the laser onto the tip apex. Emitted electrons are detected by a position-sensitive detector in front of the tip. The polarization angle \( \theta_p \) is defined in the inset, where the laser beam propagates toward the reader’s eye (see the text for further description). (b) shows a schematic defining the orthogonal angle between the laser propagation direction and the tip axis. The right angle is where \( x \) is maximum. (c) shows tip positions in \((x,y)\) coordinates for different \( \theta \) found while the tip apex is kept in the focus of the laser. The angle which gives maximum \( x \) is defined as \( \theta = 0 \) for convenience.

(3 \( \times \) 10\(^{-10}\) mbar). Laser pulses are generated in a Ti:sapphire oscillator (center wavelength of 800 nm, repetition rate of 76 MHz, and pulse width of 55 fs) and introduced into the vacuum chamber. An aspherical lens (focal length \( f = 18 \) mm) is mounted on a holder that is movable along the \( y \) direction and located just next to the tip to focus the laser onto the tip apex; the diameter of the focused beam is approximately 4 \( \mu \)m \((1/e^2\) radius\)) measured by a method with a razor blade. Linearly polarized laser light was used. The polarization vector can be changed within the transversal \((x,z)\) plane by using a \( \lambda/2 \) plate. As shown in the inset, the laser propagates toward the reader’s eye as denoted by the circled dot, the polarization angle \( \theta_p \) is defined by the angle between the tip axis and the polarization vector.

The tip can be heated to clean the apex and also negatively biased for field emission. Although the tip is polycrystalline tungsten, heating to around 2500 °C leads to the tip apex being crystallized and oriented toward the (011) direction. A position-sensitive detector with a Chevron-type double-channel-plate amplifier in front of the tip is used to record the emission patterns. The spatial resolution of field-emission microscopy (FEM) is approximately 3 nm.
In the simulations, we only used a center wavelength of 800 nm, even though the laser pulse has a spectral width of $\Delta \lambda = 25$ nm with respect to the center wavelength. Justification of the use of only a center wavelength is done by simulating the local electric fields with laser light of wavelengths of 750 and 850 nm. Figure 2(f) shows the time-averaged field distributions around the model tip obtained by excitation with these three wavelengths. They are almost the same, which indicates that the substantial spectral width of the light around 800 nm would not affect the position of the maximum local electric fields simulated with the wavelength of 800 nm.

III. OPTICAL CONTROL OF FIELD-EMISSION SITES AND EMISSION MECHANISM

A. Experimental results

The field-emission pattern from the clean tungsten tip apex which orients toward the $(011)$ direction is shown in Fig. 3(a). The most intense electron emission is observed around the $(310)$-type facets and weaker emission from $(111)$-type facets. These regions are highlighted by green (gray) areas with white edges on the schematic front view of the tip apex in the inset of Fig. 3(a). The intensity map roughly represents a work-function map of the tip apex: the lower the work function, the more electrons are emitted. The relatively high work functions of $(011)$- and $(001)$-type facets suppress the field emission from those regions.

The LFEM image in Fig. 3(b), taken with the light polarization oriented parallel to the tip axis ($\theta_p = 0$), shows a striking difference in symmetry compared to that of the FEM image in Fig. 3(a). Emission sites are the same in both cases, but the emission pattern becomes strongly asymmetric with respect to the shadow (right) and exposed (left) sides to the laser incidence direction. The most intense emission is observed on the shadow side as illustrated in the inset of Fig. 3(b). Figures 3(c) and 3(d) give the same comparison for a different azimuthal orientation of the tip as shown in the inset of Figs. 3(c). In the magnified image in Fig. 3(c), two emission sites can be identified, which are separated by approximately 30 nm. The strong emission asymmetry is observed even over such short distances, as shown in Fig. 3(d). Actually, the laser pulses arrive at an angle of $20^\circ$ off the horizontal line in both LFEM images, as indicated by the dashed red arrow in the inset of Fig. 3(a). This oblique incidence slightly affects the symmetry with respect to the central horizontal line in the observed LFEM images (see below).

The asymmetry in LFEM images can be controlled further by changing $\theta$. In Fig. 4, the $\theta$ dependence of LFEM images at $[\varphi = 0^\circ, \theta_p = 0^\circ]$ is shown, which were taken at $V_{tip} = -1500$ V and $P_L = 20$ mW. $\theta$ is varied from $\theta = -12^\circ$ to $12^\circ$ by $4^\circ$ steps. Schematics for the experimental configuration are shown at the top, in which red arrows indicate the laser propagation direction. The corresponding FEM images, which were taken at $V_{tip} = -2200$ V, are also shown. As $\theta$ increases, the asymmetry of the LFEM images becomes clearly enhanced. At $\theta = 12^\circ$, electrons are emitted almost only from right-side emission sites. Among these $\theta$ values,
distributions to the asymmetry of the LFEM images, we distinguish between the contributions of dc and laser field. The symmetry of the FEM images changed only slightly due to the laser field-induced asymmetry.

FIG. 3. (Color online) Electron emission patterns for two orthogonal azimuthal orientations ($\varphi$) of the tip without laser [(a) $\varphi=0^\circ$ and (c) $\varphi=90^\circ$], and with laser irradiation [(b) $\varphi=0^\circ$ and (d) $\varphi=90^\circ$]. $V_{tip}$ indicates the dc potential applied to the tip and $P_L$ indicates the laser power measured outside the vacuum chamber. The insets in (a) and (c) show the front view of the atomic structure of a tip apex with a curvature radius of 100 nm, based on a ball model, in which green areas with white edges indicate the field-emission sites and the dashed red arrow indicates the laser propagation direction. The inset in (b) shows a schematic side view of the laser-induced field-emission geometry, in which green (gray) vectors indicate intensities of electron emission and the white arrow indicates the laser propagation direction. A dashed white line denotes a mirror symmetry line of the atomic structure in each picture. In (c) and (d) specific regions of interest, marked by dashed red (light gray) rectangles, are blown up on the right-hand side.

FIG. 4. (Color online) $\theta$ dependence of LFEM images at [$\varphi=0^\circ$, $\theta_P=0^\circ$], which were taken at $V_{tip}=-1500$ V and $P_L=20$ mW. $\theta$ is varied from $\theta=-12^\circ$ to $\theta=12^\circ$ by 4° steps. Schematics for the experimental configuration are shown at the top, in which red (gray) arrows indicate the laser propagation direction. The corresponding FEM images are also shown below, which were taken at $V_{tip}=-2200$ V. The white dashed lines in the pictures denote a mirror symmetry line of the atomic structure. The total yield $S_{right}$ from right side of each image and the total yield from left side $S_{left}$ with respect to the white dashed line were taken. The ratio of $S_{right}$ to $S_{left}$ is plotted in the graph. Blue circles are for LFEM and black squares for FEM.

We also found experimentally a strong dependence of the electron emission patterns on the laser polarization direction and on the azimuthal tip orientation. Figure 5 shows the LFEM patterns for different values of $\theta_P$ in 30° steps, and for four different azimuthal orientations $\varphi$ of the tip. The corresponding FEM images are also shown in the leftmost column; they show simply the azimuthal rotation of the low work-function facets around the tip axis. Throughout the whole image series, the emission sites do not change, but the intensities are strongly modulated resulting in highly asymmetric features. For instance, for [$\varphi=0^\circ$, $\theta_P=0^\circ$] the intense emission sites are located on the right-hand (shadow) side of the tip, but for [$\varphi=0^\circ$, $\theta_P=60^\circ$] the emission sites on the left-hand side become dominant. LFEM images recorded for $\theta_P=180$° (not shown) are exactly the same as those for $\theta_P=0^\circ$, and all the LFEM images are well reproducible.

B. Simulations of local fields

When a laser pulse illuminates the metallic tip, surface EM waves are excited, which propagate around the tip apex.
as illustrated schematically in Fig. 2(a). Due to the resulting interference pattern, the electric fields show an asymmetric distribution over the tip apex, depending also on the laser polarization. Figure 6(a) shows the time evolution of laser fields at 800 nm wavelength over a cross section of the model tip while propagating through the tip apex from left to right, where the polarization vector has been chosen parallel to the tip axis ($\theta_p=0^\circ$). It can be seen that a surface EM wave is propagating around the tip apex indicated by white arrows and enhanced at the tip apex. The calculated time-averaged field distribution around the tip apex is shown in Fig. 6(b). The field distribution is clearly asymmetric with respect to the tip axis, with a maximum on the shadow side of the tip. The field enhancement factor of the maximum point is 2.5 with respect to the maximum field value of the incident laser, and 1.7 for the counterpart of the maximum point on the side exposed to the laser. This is consistent with our observations in Figs. 3(b) and 3(d) where the field emission is enhanced on the shadow side.

Additionally, we would like to note that a similar asymmetric distribution can also be seen even for a metal with a dielectric function, which is largely different from that of tungsten. For example, we performed a simulation for gold using a real part Re($\varepsilon$) = -24 and an imaginary part Im($\varepsilon$) = 1.5. Figure 6(c) shows the time-averaged field distribution on the gold tip apex. The field distribution shows a similar asymmetry as for tungsten. It should also be mentioned that surface EM waves are classified in terms of the dielectric functions of the interacting material, although some authors do not distinguish. If the real part of the dielectric function is negative, then the surface EM waves are proper surface plasmon polaritons. On the other hand, if the real part is positive and the imaginary part is large, the term Zenneck waves is more appropriate. The dielectric functions of tungsten and gold between 700 and 900 nm are plotted by black dots in Fig. 6(d), where the values at 800 nm are highlighted by red circles. From Fig. 6(d), strictly speaking, the excited surface EM waves on tungsten are Zenneck waves and those on gold are surface plasmon polaritons. Figures 6(b) and 6(c) also indicate that different kinds of surface EM waves do not show substantial difference in the resulting field distribution.

The asymmetric local-field distribution can be controlled by changing the polar angle $\theta$ and the laser polarization angle $\theta_p$. Figure 6(e) shows time-averaged field distributions on the tungsten tip apex with different laser incidence directions relative to the polar orientation of the tip apex. As $\theta$ increases, the asymmetry becomes stronger. This is consistent with our observation in Fig. 4 where the most asymmetric emission is observed at $\theta = 12^\circ$. Figure 6(f) shows, in a front view, time-averaged field distribution maps from the white dashed line region of the model tip in Fig. 6(b). This area corresponds roughly to the observed area in our experiments. The dashed red arrows indicate the laser propagation direction, which has been set to be the same as in our experimental situation. The field distribution changes strongly depending on the polarization angle. While the maximum field is located directly on the shadow side of the tip for $\theta_p=0^\circ$, the maximum moves toward the lower side of the graphs in concert with the polarization vector for $\theta_p=30^\circ$ and $60^\circ$, and reappears on the upper side for $\theta_p=120^\circ$ and $150^\circ$. For $\theta_p=90^\circ$ the polarization vector is perpendicular to the tip axis and produces two symmetric field lobes away from the tip apex. In general the observed LFEM images show the same intensity modulations (Fig. 5): each LFEM pattern at $\theta_p=30^\circ$ and $60^\circ$ shows pronounced emission at the lower side of the image, while each LFEM pattern at $\theta_p=120^\circ$ and $150^\circ$ has maximum emission at the upper side of the image.

C. Simulations of LFEM by the photofield-emission model

From the calculated local fields, we further simulated the LFEM images by considering the photofield-emission mechanism. The current density $j_{calc}$ of field emission can be described in the Fowler-Nordheim theory based on the free-electron model as follows:

$$j_{calc} = \frac{A \phi^2}{E^{3/2}}$$

where $j_{calc}$ is the current density, $\phi$ is the work function, and $E$ is the electric field. This equation is valid for electric fields above the threshold value $E_{th}$.
Fig. 6. (Color online) (a) Time evolution of laser fields over a cross section of the model tip while propagating through the tip apex from left to right. The polarization vector is parallel to the tip axis (θp=0°). Small black arrows indicate the field direction, and field strength is represented by a linear color scale: highest field values are represented in yellow (white). The time-averaged field distribution for tungsten and gold tips is shown in (b) and (c) where the model tip of Fig. 2(b) is employed for both. The dielectric functions of tungsten and gold for the wavelengths between 700 and 900 nm are plotted by black dots in (d) and the values at 800 nm are highlighted by red circles. (e) shows the time-averaged field distributions around the tungsten tip for three different polar angles: θ =−12°, 0°, and 12°. In (f) the time-averaged field distributions are given in a front view of the model tip for different polarization directions θp (θ=0°). The laser propagation direction is indicated by dashed red arrows and is the same as in the experiment.

\[
\dot{j}_{cal} = \frac{em}{2\pi^2\hbar^3} \int_{-W_g}^{\infty} \int_{-W_a}^{W_a} D(W,\Phi,F)f(E)dWdE. \tag{1}
\]

Here, e is the electron charge, m is the electron mass, −W_g is the effective constant potential energy inside the metal, W is the normal energy with respect to the surface, and E is the total energy. Important factors are \(D(W,\Phi,F)\) and \(f(E)\). \(D(W,\Phi,F)\) is the probability that an electron with the normal energy \(W\) penetrates the surface. It depends exponentially on the triangular-shaped potential barrier above \(W\), as indicated by the cross-hatched area in Fig. 7(a) where field emission with energy \(W\) occurs. The cross-hatched area is determined by the work function \(\Phi\) and the electric field \(F\) just outside the surface. \(f(E)\) is an electron distribution function. In the case of field emission we have \(F=F_{DC}\), where \(F_{DC}\) is the applied dc electric field, and \(f(E)\) is the Fermi-Dirac distribution, respectively.

Dirac distribution at 300 K as shown in Fig. 7(a). In the photofield-emission model, \(F\) still equals \(F_{DC}\), but the electron distribution is strongly modified by the electron-hole pair excitations due to single-photon and multiphoton absorptions, resulting in a nonequilibrium distribution characterized by a step-like profile, as illustrated in Fig. 7(b). For example, one-photon absorption creates a step of height \(S_1\) from \(E_F\) to \(E_F+h\nu\) by exciting electrons from occupied states between \(E_F−h\nu\) and \(E_F\). Absorption of a second photon creates a step of height \(S_2\) from \(E_F+h\nu\) to \(E_F+2h\nu\), where \(S_2=S_1^2\). We included absorption of up to four photons. The step height \(S_1\) is proportional to the light intensity \(I\). In the vicinity of the tip we have \(I=I_{FDC}\), where \(I_{FDC}\) is the enhanced optical electric field that varies over the tip apex as illustrated in Fig. 6(f).

There are three adjustable parameters in our calculations of \(j_{cal}\): \(\Phi\), \(F_{DC}\), and \(S_1\). They are all functions of position on the tip apex. \(\Phi\) and \(F_{DC}\) maps on the tip apex were obtained from the measured FEM images. The measured FEM images, which were symmetrized to have the ideal twofold symmetry, represent the current density \(j_{exp}\) as a function of position on the tip apex, because the electrons follow closely the field lines from the tip apex to the position-sensitive detector. In practice we assumed a radius of curvature of the tip apex of 100 nm and used the FEM image at \(\varphi=45°\) shown in Fig. 5. A relative dc field \(F_{DC,relative}\) distribution was generated by \(\Phi_{exp}\). We used a more wirelike tip shape for this purpose as shown in Fig. 8(a), and a grounded plate was set 1 cm away from the tip, which is close to that in our experimental setup. The simulated \(F_{DC,relative}\) is shown in Fig. 8(b), which is normalized by the value at tip apex. Going away from the tip apex \(F_{DC,relative}\) decreases. A scaling factor \(\alpha\) is introduced, which determines \(F_{DC}\) by \(F_{DC}=\alpha F_{DC,relative}\). We then obtained the \(\Phi\) map by inserting \(F_{DC}\) into Eq. (1) and postulating \(j_{exp}−j_{cal}=0\). The resulting \(\Phi\) map was compared to known values for several surface facets of tungsten. The scaling factor \(\alpha\) was changed and the procedure was iterated until reasonable work functions were obtained. Thus, a full \(\Phi\) map and absolute values for \(F_{DC}\) were determined.

A line profile of the resulting \(\Phi\) map along the (001)-(011)-(001) curve is shown in Fig. 8(c). The work function has local curve maxima at the (011)- and (001)-type facets and local minima at (310)-type facets, which is in line with the observed field-emission intensity distribution seen in Fig. 3(a); the higher the work function, the lower the intensity.

Fig. 7. (Color online) (a) A schematic of field emission from a Fermi-Dirac distribution, where an electron with a normal energy \(W\) is emitted. The surface barrier above \(W\) is shown by a cross-hatched area. (b) and (c) show schematics of photofield emission from a nonequilibrium electron distribution and optical field emission from a Fermi-Dirac distribution, respectively.
LASER-INDUCED FIELD EMISSION FROM A TUNGSTEN...

FIG. 8. (Color online) The calculated dc field distribution around the model tip is shown in (a). A wirelike shape was employed for the simulation of relative dc fields. The color scale is the same as in Fig. 6. The relative dc field distribution at the tip apex of (a) is shown as a function of angle \(\theta_c\), which is defined in (a). The obtained work-function profile along a (001)-(011)-(010) curve is shown in (c) as a function of \(\theta_c\). The resulting values are summarized for several facets and compared with known experimental values in Table I. They are in fair agreement with each other. A field strength \(F_{\text{DC}}\) of 2.15 V/nm results at the tip apex center for the FEM image taken with \(V_{\text{tip}}=2250\) V, which is a typical value for FEM.

The LFEM experiments were carried out with a reduced tip voltage \(V_{\text{tip}}=\pm 1500\) V. Therefore, we used a down-scaled value of 1.43 V/nm in the LFEM simulations. Note that the uncertainty in the \(\Phi\) values is not important for our conclusions, which will be discussed below: we have also checked the whole discussion in this section with a different work-function map using 4.6, 4.32, and 4.20 eV for (011), (001), and (310) facets, respectively, but the main outcome does not change.

Substituting the obtained \(\Phi\) and \(F\) distribution maps into Eq. (1), and using a nonequilibrium electron distribution \(f(E)\), the absolute values of \(S_1\) over the tip apex were determined by fitting the measured total current from the (310) facet on the right-hand side of the LFEM image in Fig. 3(b). The resulting maximum value for \(S_1\) was \(1.6 \times 10^{-6}\). By substituting all the adjusted parameters into Eq. (1), we could simulate all the LFEM images. The calculated current densities on the tip apex were projected to the flat screen by following the static field lines. The simulated images can now directly be compared to the experimental images (Fig. 5): they are in excellent agreement in every detail. This comparison clearly demonstrates that the observed strongly asymmetric features originate from the modulation of the local photofields.

D. Simulations of LFEM by the optical field-emission model

We also simulated the LFEM images for the optical field-emission process and compared the resulting intensity distributions to those of the photofield-emission model. In the optical field-emission model schematically shown in Fig. 7(c), the Fermi-Dirac distribution is not modified, but instead the electric field \(F\) in Eq. (1) is expressed as \(F=F_{\text{DC}}+F_{\text{laser}}\), where \(F_{\text{laser}}\) is the normal component of \(F_{\text{laser}}\) at each point of the tip surface. The absolute values for \(F_{\text{laser}}\) on the tip apex were determined in the same way as described above for \(S_1\). The resulting maximum value for \(F_{\text{laser}}\) was 0.71 V/nm.

Figure 9(a) shows the LFEM image for the optical field-emission process together with experimentally obtained LFEM and the simulated LFEM image based on the photofield-emission model at \([\varphi=0^\circ, \theta_p=0^\circ]\). The optical field-emission model results in an even more strongly asymmetric pattern as compared to the photofield-emission model. This contrasts with the experimental data. Figure 9(b) shows line profiles extracted from the observed FEM images (red line with squares), LFEM images (dashed blue (light gray)), and from LFEM images simulated by the photofield-emission model (green solid line) and the optical field-emission model (black dashed line) at \([\varphi=0^\circ, \theta_p=0^\circ]\). The whole scanned line corresponds to the unfold field indicated by the dashed blue line in the FEM figures above, and the corresponding sides are indicated by white arrows. Each line profile has been normalized by the maximum value.

![Figure 8](image1.jpg)  
**FIG. 8.** (Color online) The calculated dc field distribution around the model tip is shown in (a). A wirelike shape was employed for the simulation of relative dc fields. The color scale is the same as in Fig. 6. The relative dc field distribution at the tip apex of (a) is shown as a function of angle \(\theta_c\), which is defined in (a). The obtained work-function profile along a (001)-(011)-(010) curve is shown in (c) as a function of \(\theta_c\). The resulting values are summarized for several facets and compared with known experimental values in Table I. They are in fair agreement with each other. A field strength \(F_{\text{DC}}\) of 2.15 V/nm results at the tip apex center for the FEM image taken with \(V_{\text{tip}}=2250\) V, which is a typical value for FEM.

The LFEM experiments were carried out with a reduced tip voltage \(V_{\text{tip}}=\pm 1500\) V. Therefore, we used a down-scaled value of 1.43 V/nm in the LFEM simulations. Note that the uncertainty in the \(\Phi\) values is not important for our conclusions, which will be discussed below: we have also checked the whole discussion in this section with a different work-function map using 4.6, 4.32, and 4.20 eV for (011), (001), and (310) facets, respectively, but the main outcome does not change.

Substituting the obtained \(\Phi\) and \(F\) distribution maps into Eq. (1), and using a nonequilibrium electron distribution \(f(E)\), the absolute values of \(S_1\) over the tip apex were determined by fitting the measured total current from the (310) facet on the right-hand side of the LFEM image in Fig. 3(b). The resulting maximum value for \(S_1\) was \(1.6 \times 10^{-6}\). By substituting all the adjusted parameters into Eq. (1), we could simulate all the LFEM images. The calculated current densities on the tip apex were projected to the flat screen by following the static field lines. The simulated images can now directly be compared to the experimental images (Fig. 5): they are in excellent agreement in every detail. This comparison clearly demonstrates that the observed strongly asymmetric features originate from the modulation of the local photofields.

D. Simulations of LFEM by the optical field-emission model

We also simulated the LFEM images for the optical field-emission process and compared the resulting intensity distributions to those of the photofield-emission model. In the optical field-emission model schematically shown in Fig. 7(c), the Fermi-Dirac distribution is not modified, but instead the electric field \(F\) in Eq. (1) is expressed as \(F=F_{\text{DC}}+F_{\text{laser}}\), where \(F_{\text{laser}}\) is the normal component of \(F_{\text{laser}}\) at each point of the tip surface. The absolute values for \(F_{\text{laser}}\) on the tip apex were determined in the same way as described above for \(S_1\). The resulting maximum value for \(F_{\text{laser}}\) was 0.71 V/nm.

Figure 9(a) shows the LFEM image for the optical field-emission process together with experimentally obtained LFEM and the simulated LFEM image based on the photofield-emission model at \([\varphi=0^\circ, \theta_p=0^\circ]\). The optical field-emission model results in an even more strongly asymmetric pattern as compared to the photofield-emission model. This contrasts with the experimental data. Figure 9(b) shows line profiles extracted from the observed FEM images (red line with squares), LFEM images (dashed blue (light gray)), and from LFEM images simulated by the photofield-emission model (green solid line) and the optical field-emission model (black dashed line) at \([\varphi=0^\circ, \theta_p=0^\circ]\). The whole scanned line corresponds to the unfold field indicated by the dashed blue line in the FEM figures above, and the corresponding sides are indicated by white arrows. Each line profile has been normalized by the maximum value.

![Figure 9](image2.jpg)  
**FIG. 9.** (Color online) (a) Experimentally obtained LFEM image and simulated LFEM image at \([\varphi=0^\circ, \theta_p=0^\circ]\) for both photofield-emission and optical field-emission models. (b) shows line profiles extracted from the observed FEM images (red line with squares), LFEM images (dashed blue (light gray)), and from LFEM images simulated by the photofield-emission model (green solid line) and the optical field-emission model (black dashed line) at \([\varphi=0^\circ, \theta_p=0^\circ]\). The whole scanned line corresponds to the unfold field indicated by the dashed blue line in the FEM figures above, and the corresponding sides are indicated by white arrows. Each line profile has been normalized by the maximum value.
FIG. 10. (Color online) Laser power and tip voltage dependence of the electron emission patterns at [φ=0°, θF=0°]. On the vertical axis laser power and on the horizontal axis tip voltage are plotted. The inset shows the electron emission patterns where the laser beam is displaced from the tip apex downward by distances of 1 and 16 μm, taken at the 90 mW laser power. The definition of distance d is also shown on the right-hand side of the inset. The time-averaged field distribution around the tip when the laser beam is displaced by a distance of 0.5 μm is also shown in the inset, where the longer model tip shown in Fig. 2(e) was used. The green dashed circles highlight the left-side electron emission sites (see Sec. IV B).

IV. VOLTAGE AND POWER DEPENDENCE OF EMISSION PROCESSES

A. Lower laser power

In this section, we further discuss the details of electron emission processes and their dependence on laser power and tip voltage by investigating electron emission patterns and Fowler-Nordheim plots and by simulating electron energy distributions. Figure 10 shows the dependence of LFEM images at [φ=0°, θF=0°] on the average laser power PL and the tip voltage Vtip applied to the tip. Throughout the whole series of pictures, the intensity of each image was normalized by the maximum intensity. Normally, total yields decrease as either laser power or tip voltage decreases. As can be seen, the left-right asymmetry is present in all images below a laser power of 60 mW except when PL=0 mW (FEM). Nevertheless, the images show a trend: the outlines of emission facets become diffuse in the lower tip voltage region (see, e.g., the 20 mW row surrounded by a white dashed line). In these experiments, electron emission is considered to be a concerted action of photoemission and field emission. In the case of field emission, the emitted electrons strongly feel the work-function corrugation on the nanometer scale, which generates sharp contrasts at the border of each emission facet. In the case of photoemission, the excited electrons encounter a much narrower surface barrier and appear thus to be less sensitive to the work-function corrugation, hence showing a smeared contour of the emission sites. At lower tip voltage, multiphoton processes will be enhanced since field emission is suppressed. Eventually, photoemission from three-photon photoexcitation (3PPE) or four-photon photoexcitation (4PPE) will contribute, with energies above the vacuum level. Therefore, the outline of each emission facet becomes diffuse in the lower tip voltage region. This is confirmed by simulations of energy distribution curves and emission patterns.

We have simulated the energy distribution of field-emitted electrons with the parameters representing the emission site where maximum intensity can be seen in the simulated image in Fig. 5 at [φ=0°, θF=0°]: the work function at this point is 4.45 eV, the dc field is 1.32 V/nm, and S1 is 1.6 × 10^{-6}, which should correspond to the conditions where the most intense point can be seen in the image at 20 mW laser power and -1500 tip voltage in Fig. 10. Figure 11(a) shows the corresponding simulated energy spectrum at the top, and...
underneath, spectra for various lower tip voltages. We find that field emission from two-photon processes is strongly dominant at the higher dc fields. For lower dc voltage, the calculated energy distributions clearly show that field emission from the two-photon photoexcitation (2PPE) line is suppressed and photoemission from the 3PPE line is enhanced. The simulated LFEM images at corresponding tip voltage are shown in Fig. 11(b). As the dc voltages decrease, the outlines of emission sites become diffuse due to the fact that photoemission processes become dominant. This is in line with the experimental observations described above.

Experimental FN plots give further support for the suggested emission mechanism. Figure 12 shows FN plots of FEM and LFEM, where the electron count rate $i$ divided by $V_{tip}^2$ is displayed on a logarithmic scale versus the inverse of $V_{tip}$. The count rate was taken by integrating the electron emission from the right-hand (310)-type facet of each image in Fig. 10. The horizontal axis is $1/V_{tip}$.

![Figure 12](image)

**FIG. 12.** (Color online) FN plots for FEM and LFEM ($P_L = 10$, 20, 30, 40, and 50 mW). The vertical axis is signal $i$ over $V_{tip}^2$ on a logarithmic scale. The signal $i$ is the total yield of electron emission from the right-hand (310)-type facet of each image in Fig. 10. The horizontal axis is $1/V_{tip}$.

The slope of the straight sections is proportional to $\Phi^{-3/2}$. From this fact, we can estimate the effective barrier heights $\Phi_{LFEM(10 \, mW)}$ and $\Phi_{LFEM(20 \, mW)}$ at $P_L = 10$ and 20 mW, respectively, which an emitted electron feels in the case of LFEM. First, the barrier height ratios were derived from the proportionality constants $\Phi_{LFEM(10 \, mW)}/\Phi_{FEM} = 0.24$ and $\Phi_{LFEM(20 \, mW)}/\Phi_{FEM} = 0.2$. Taking the work function of (310)-type facets of 4.35 eV for $\Phi_{FEM}$, thus $\Phi_{LFEM(10 \, mW)} = 1.05$ eV and $\Phi_{LFEM(20 \, mW)} = 0.85$ eV were obtained. The energy difference between $\Phi_{LFEM}$ and $\Phi_{FEM}$ should correspond to the energy of emitted electrons measured from the Fermi level in LFEM. Here, we obtain $\Phi_{LFEM(10 \, mW)} - \Phi_{FEM} = 3.3$ eV and $\Phi_{LFEM(20 \, mW)} - \Phi_{FEM} = 3.5$ eV, which are close to the electron energy after two-photon excitation, i.e., 3.1 eV. These values corroborate the two-photon photofield-emission processes, which is consistent with the simulated electron energy distributions for higher voltage in Fig. 11(a).

**B. Higher laser power**

For this discussion, we would like to point out the electron emission from the shank side of the tip in the higher laser power range. As in the previous sections, the electron emission from the tip apex is dominant in the emission pattern at low laser power because of the local-field enhancement at the tip apex even though the surface area exposed to the laser beam is much larger for the shank than for the apex. At the higher laser power, however, the electron emission from the shank side becomes noticeable because of the nonlinear dependence of the electron emission intensities on the laser power.

In the column of $V_{tip} = -100 \, V$ in Fig. 10, the left-side electron emission features highlighted by green dashed circles become suddenly very strong for laser powers exceeding 70 mW. At 90 mW, the intensity of left-side electron emission is comparable to that on the right side. It remains even when the position of the tip in the beam waist is varied. The insets of Fig. 10 show electron emission patterns at 90 mW laser power where the laser beam is displaced from the tip apex downward by distances of 1 and 16 $\mu m$. In the two images, right-side emission sites disappear, but the left-side emission remains, indicating that it originates from the shank side of the tip. Such an electron emission should be dominated by photoemission over the surface barrier because dc fields on the shank side are significantly weak with respect to the tip apex. Since the laser pulses arrive at an angle of $20^\circ$ off the horizontal line in both LFEM images, the position of the electron emission from the shank is also deviated from the horizontal line. In the inset, we also show the time-averaged field distribution around the tip when the laser beam is displaced downward from the tip apex by a distance of 0.5 $\mu m$: the longer model tip shown in Fig. 2(e) was used. The maximum field can be observed at the side exposed to laser, which is consistent with our observations.

**V. CONCLUSIONS**

We have observed laser-induced modulations of field-emission intensity distributions resulting in strong asymmetries, which originate from the laser-induced local fields on the tip apex. By varying the laser polarization and the laser incidence direction relative to both azimuthal and polar orientation of the tip apex, we have demonstrated the realization of an ultrafast pulsed field-emission source with convenient control of nanometer-sized emission sites. These experimental observations are quantitatively reproduced by using simulated local fields for the photofield-emission model. We discussed the emission processes further and
found field emission after two-photon photoexcitation to be the dominant process in laser-induced field emission. From experimental data and simulations, the dependence of the emission processes on laser power and tip voltage could be understood.

This type of electron source is potentially useful for many applications such as time-resolved electron microscopy, spatiotemporal spectroscopy, near-field imaging techniques, surface-enhanced Raman spectroscopy, or coherent chemical reaction control. Maybe the most interesting applications will arise when two laser pulses with different polarizations or paths are used for the emission of two independent electron beams from two different sites on the tip, spaced only a few tens of nanometers apart, and with an adjustable time delay between the two electron pulses. Since field-emission electron sources produce highly coherent electron beams due to their inherently small source size, comparable to the finite spatial extent of electron wave packets inside the source, we could expect two spatially and temporally coherent electron beams to be available within the coherence time. This should create opportunities for addressing fundamental questions in quantum mechanics, such as anticorrelation of electron waves in vacuum, or create future directions in electron holography.

28 Note that the diameter of the focused beam in the simulation (1 μm) is smaller than that in the experiments (4 μm) because selecting a narrower focus reduces the computational costs. This is expected to have only a minor impact on the simulated emission patterns, because the size of the focus is still sufficiently larger than the size of tip apex (0.1 μm), resulting in a roughly constant optical field in the vicinity of the tip apex.
