Radical trachelectomy is a fertility-preserving alternative to radical hysterectomy in carefully selected young women with early-stage cervical cancer. However, in cases with subsequent severe cervical stenosis, assisted reproductive techniques can be difficult. This is a case report of a 34-year-old patient who underwent robot-assisted radical trachelectomy and cerclage for early-stage (IB2) adenosquamous carcinoma. Three months after surgery, the patient underwent ovarian stimulation using a gonadotropin-releasing hormone antagonist protocol. As it was impossible to perform transcervical embryo transfer due to the almost complete absence of the cervical opening, transmyometrial embryo transfer under ultrasound guidance was performed. This resulted in a successful singleton pregnancy. This is the first case of successful pregnancy conceived by in vitro fertilization with transmyometrial embryo transfer in a patient who had previously undergone robot-assisted radical trachelectomy.

Keywords: Embryo transfer; Fertility preservation; Oocyte retrieval; Trachelectomy; Uterine cervical neoplasms

Introduction

Early detection of cervical cancer increases the chance that fertility-preserving surgery can be performed. However, embryo transfer can be complicated by cervical abnormalities, such as cervical stenosis, atresia, or previous trachelectomy. According to two previous studies, the live birth rate after radical trachelectomy appears to be around 64%–67%, and most pregnancies are supported by intrauterine insemination or in vitro fertilization (IVF). Reasons for infertility after trachelectomy include cervical stenosis, decreased cervical mucus, and decreased vasculature supplying the uterus, according to previous studies [1,2]. The rate of cervical stenosis due to cervical cancer only or cervical trachelectomy in cases of difficult embryo transfer is challenging to obtain. In about 1% of cases, experienced experts have found cervical embryo transfer to be difficult due to anatomical and pathological cervical disorders [3]. Doctors may try traumatic transcervical embryo transfer, cervical dilation (with or without hysteroscopy), and transmyometrial embryo transfer (TMET) in such patients.

Kato et al. [4] introduced the Towako method for TMET and achieved several successful cases of pregnancy using this method. The Towako set consists of a needle/stylet and transfer catheter. Under transvaginal ultrasonography (TV-USG) guidance, a needle is inserted transmyometrially between the upper cervix and lower bladder. When the needle reaches the uterine cavity, it is pulled back until the tip becomes clearly visible at the center of the endometrium. The inner catheter—loaded with one embryo in the culture medium—is then moved through the outer catheter, and the embryo is deposited in the uterine cavity [4]. A retrospective study showed an im-
plantation rate of 9.5%, with pregnancy and miscarriage rates of 25% and 30%, respectively, after TMET [3].

There have been no reports of pregnancy with TMET after robotic trachelectomy. Herein, we introduce the first successful case of pregnancy with TMET after robotic trachelectomy.

**Case report**

A 34-year-old woman was diagnosed with cervical intraepithelial neoplasia grade 3 with human papillomavirus 16 after a cervical punch biopsy at a local gynecological hospital in December 2019. Soon after, she was transferred to Seoul National University Bundang Hospital for further evaluation. As a result of a loop electrosurgical excision procedure, a 6-mm-deep and 11-mm-wide adenocarcinoma was found. According to magnetic resonance imaging and positron emission tomography, there was no lymph node or distant metastasis. The patient was nulligravida and wanted to become pregnant.

The oncologist classified her disease as stage IB1 (FIGO Committee on Gynecologic Oncology, 2019). Robotic radical trachelectomy, sentinel lymph node mapping, and cervical cerclage were successfully performed in March 2020. The final pathology report confirmed that the adenocarcinoma component was a mixture of the usual type and mucinous carcinoma, and that cancer might remain in the uterus.

The disease classified as stage IB2p without parametrial or lymphovascular invasion. Therefore, an additional margin was resected and an endometrial biopsy was performed; no tumor was observed. In February and May 2020, it was shown that the squamous cell carcinoma antigen level was 0.6 ng/mL, and the patient decided to postpone additional surgery and get pregnant quickly.

She had been married for 8 years, had a regular menstrual cycle from the age of 15 years, and had no history of other chronic medical or surgical disease; she was a non-smoker and had no history of hirsutism or galactorrhea. Her physical examination was uneventful, except for severe cervical stenosis without a cervical opening. A hormonal work-up showed a normal profile with a day-3 follicle-stimulating hormone (FSH) concentration of 2.05 mIU/mL and an anti-Müllerian hormone level of 1.52 ng/mL. Hysterosalpingography was normal. Her male partner was 39 years old and had no significant medical history. A semen analysis showed decreased motility (33%) 5 years ago.

Ovarian stimulation using a gonadotropin-releasing hormone (GnRH) antagonist protocol and IVF/intracytoplasmic sperm injection (ICSI) were selected, considering the patient’s age, cervical status, and borderline ovarian reserve. The patient’s last menstrual period was June 12 and human FSH (300 IU/day; Gonal-F, Merck Serono, Middlesex, UK) was injected subcutaneously from June 14 to 21. Day 5 TV-USG showed a normal uterus and ovaries. Each ovary had dominant follicles measuring 11–12 mm and a total antral follicle count of eight follicles. Subcutaneous injection of 0.25 mg of GnRH antagonist (Cetrotide; Serono, Geneva, Switzerland) was performed on day 6 for 4 days. On day 9, TV-USG showed two dominant follicles with mean diameters of 18 mm or more and an endometrial thickness of 9.7 mm. On the same day, 250 μg of recombinant human chorionic gonadotropin (hCG; Ovidrel, Sereno) was administered subcutaneously on the same day to induce ovulation.

The estradiol level on the hCG day was 2,604 pg/mL, and the progesterone level was 0.84 ng/mL. Oocyte retrieval was performed 36 hours after hCG injection under TV-USG guidance. A total of 11 oocytes were retrieved, including three oocytes in metaphase II. ICSI was performed for all available oocytes due to the poor sperm parameters. On day 1, four oocytes showed two pronuclei, which were cleaved into two good-quality embryos (10A and 6A-com). Two embryos were discarded, and one embryo was cryopreserved in a blastocyst (ErB-AB).

As it was impossible to perform transcervical embryo transfer due to the almost complete absence of the cervical opening, TMET under ultrasound guidance was performed using a Towako transfer set (Towako needle; Cook, Eight Mile Plains, Australia) (Figure 1). The pa-

tient was premedicated with 3 mg of midazolam administered intra-
venously (IV) and fentanyl (100 μg; IV); both were administered 10
minutes before the procedure. One embryo (EdB-AB) was transferred
successfully on the fifth day after oocyte retrieval. There were no ma-
jor complications, including pain, bleeding, infection, or injuries. Bio-
chemical pregnancy was confirmed 15 days after post-oocyte re-
trieval by a measurement of serum β-hCG (140.83 mIU/mL). An in-
trauterine fetal heart was confirmed by TV-USG at 7 weeks’ gestation.

Discussion

As early detection of gynecological cancers has become possible,
there have been increasingly many patients desiring fertility preser-
vation, particularly in patients with cervical cancer. In cases of stage
IB1 cancer and when the tumor 2 cm or smaller, radical trachelecto-
my and pelvic lymph node dissection with (or without) para-aortic
lymph node dissection may be presented as an option, and abdomi-
nal tracheectomy can be performed even if the tumor is 2 cm or
larger [5]. After tracheectomy, cervical dilation is difficult, and it is
difficult to reach the fundus.

Our patient underwent robot-assisted radical tracheectomy with
clinical-stage IB1 disease, but the final pathology report confirmed
that the adenocarcinoma component was a mixture of the usual
type and mucinous carcinoma, and it was found that cancer might
remain in the uterus. Thus, additional resection margins and an en-
dometrial biopsy were conducted, with no residual cancer as a result.
Because the patient prioritized pregnancy, the consideration of any
additional surgery was postponed.

Unlike other cases reported previously, the patient presented herein
prioritized pregnancy and attempted to become pregnant immedi-
ately after surgery without proper follow-up to determine whether
there was recurrence. In our case, for a fast pregnancy, TMET was per-
fomed immediately after tracheectomy, and a successful pregnancy
was achieved.

With the development of assisted reproductive technology tech-
nology, it is important to increase the implantation and pregnancy
rates through appropriate embryo transfer. According to a retrospec-
tive observational study, it was estimated that a poor embryo trans-
fer technique accounted for 30% of all IVF failures. Embryo transfer
was difficult in about 7.7% of all procedures, and the clinical pregna-
cy rate (CPR) was significantly lower than in non-difficult procedures
(27.1% vs. 38.2%, p < 0.001). The CPR decreased progressively with
the use of additional maneuvers during embryo transfer, including
the use of an outer catheter sheath, Wallace stylet, and tenacula [6].

If there are cervical abnormalities, such as cervical stenosis, atresia,
or previous tracheectomy, the likelihood of needing an additional
maneuver increases. In such cases, TMET can be considered. Accord-
ing to Khairy et al. [7], when performing TMET, endometrial trauma
and myometrial contraction can be reduced by minimizing the pro-
cedure time, and the risk of contamination of the embryo catheter
and infection can be reduced by not passing through cervical secre-
tions.

In a previous report, a patient had cervical cancer (1A2) and at-
tempts a natural pregnancy for 6 months after radical vaginal trac-
heectomy and laparoscopic pelvic lymph node dissection 3 years
previously; however, she was unsuccessful. As a result, she tried IVF
using a GnRH agonist long protocol with TMET and was presented as
a case of successful pregnancy [8]. Another patient had a distorted
internal cervical canal and cervical dilation failed repeatedly. She also
achieved pregnancy by TMET [9].

Khairy et al. [7] compared the outcomes of “very difficult transcervi-
cal embryo transfer” (vdTCET) versus TMET in 174 patients. They
defined vdTCET as requiring more than two tenacula or stylets,
changing the embryo transfer catheter, reloading of the embryos or
canceling the procedure, and freezing the embryo to transfer after
cervical dilatation. The clinical pregnancy and live birth rates for
TMET (32.6% and 25%, respectively) were higher than those for vd-
TECT (26.1% and 16.4%, respectively). These studies have shown that
TMET is a good alternative for difficult embryo transfer cases where
cervical embryo transfer cannot be achieved.

During the follow-up period, it is necessary to check for miscar-
riage, live birth, or recurrence of cervical cancer. This is the first case
of successful pregnancy conceived by IVF with TMET for a patient
who had previously undergone robot-assisted radical tracheectomy.
In the future, it may be meaningful to consider providing the options
of ART and TMET in women of childbearing age diagnosed with cer-
vical cancer when additional surgery is needed after a quick preg-
nancy.

Conflict of interest
