(Dated: November 15, 2018)

We investigate the folding and forced-unbinding transitions of adsorbed semiflexible polymer chains using theory and simulations. These processes describe, at an elementary level, a number of biologically relevant phenomena that include adhesive interactions between proteins and tethering of receptors to cell walls. The binding interface is modeled as a solid surface and the worm-like chain (WLC) is used for the semiflexible chain (SC). Using Langevin simulations, in the overdamped limit, we examine the ordering kinetics of racquet-like and toroidal structures in the presence of attractive interaction between the surface and the polymer chain. For a range of interactions, temperature, and the persistence length $l_p$ we obtained the monomer density distribution $n(x)$ ($x$ is the perpendicular distance of a tagged chain end from the surface) for all the relevant morphologies. There is a single peak in $n(x)$ inside the range of attractive forces $b$ for chains in the extended conformations while in racquet and toroidal structures there is an additional peak at $x \approx b$. The simulated results for $n(x)$ are in good agreement with theory. The formation of toroids on the surface appears to be a first order transition as evidenced by the bimodal distribution in $n(x)$. The theoretical result underestimates the simulated $n(x)$ for $x \ll b$ and follows $n(x)$ closely for $x \geq b$; the density calculated exactly agrees well with $n(x)$ in the range $x \ll b$. Chain-surface interaction is probed by subjecting the surface structures to a pulling force $f$. The average extension $\langle x(f) \rangle$ as a function of $f$ exhibit sigmoidal profile with sharp all-or-none transition at the unfolding force threshold $f=f_c$ which increases for more structured states. Simulated $\langle x(f) \rangle$ compare well with the theoretical predictions. The critical force $f_c$ is a function of
$l_s/l_c$ for a fixed temperature, where $l_c$ and $l_s$ are the length scales that express the strength of the intramolecular and SC-surface attraction, respectively. For a fixed $l_s$, $f_c$ increases as $l_p$ decreases.

I. INTRODUCTION

Interactions between biomolecules and surfaces are important in a number of biological phenomena. Binding and unbinding of proteins from macromolecular complexes are involved in the regulation of biological functions [1, 2, 3]. Adsorption of fibrinogen influences the adhesion of leukocytes, microphages or platelets. In addition, interaction between proteins, DNA and RNA are mediated by biological membranes [4, 5, 6]. In the crowded cellular conditions, protein-protein and DNA-protein interactions take place in confined geometries in which surface interactions are vital. For instance, interaction between P-selectin receptors and their specific ligands is mediated by a flat and shallow binding interface [7, 8]. Besides these situations, which are obviously relevant in biology, there are a number of situations in polymer science where interactions with surfaces are important [9, 10, 11, 12]. These include nanolubrication that involve interaction between surfaces that are mediated by polymers. Design of nanoscale materials and biologically inspired self-assembling systems also requires an understanding of how heteropolymers and biomolecules interact with surfaces. Recent advances in atomic force microscopy [7, 13, 14] has allowed a direct probe of the energetics of interaction between adsorbed proteins with other biomolecules [1, 15, 16, 17, 18, 19]. The potential applications of polymer-surface models to a number of problems has prompted us to develop a theoretical approach which can be used in conjunction with AFM experiments to decipher biomolecule-surface interactions.

There have been numerous studies of adsorption of flexible polymers adsorbed on solid surfaces which find applications in many aspects of colloidal and interface science [10, 11, 12, 20]. However, many biomolecules, including DNA, RNA, and proteins, are better described using worm-like chain (WLC) models [1, 21, 22]. Thus, it is important to provide a theoretical description of the interactions between semiflexible chains [22, 23, 24] and interfaces. The purpose

*Corresponding author phone: 301-405-4803; fax: 301-314-9404; thirum@glue.umd.edu
of this paper is to address the following specific questions: (i) It is known that DNA, a semi-
flexible polymer, undergoes a coil-globule transition in the presence of osmolytes or multivalent
cations [23, 25]. Simulations of semiflexible chains in poor solvents [20, 26] have been used to
understand the kinetics and pathways of transitions from extended conformations to collapsed
toroidal structures. The coil-globule transition in stiff chains in the bulk occurs through a series
of metastable racquet structures [20, 26]. How does the interaction with the surface alter the
morphology and kinetics of such transitions? This question is relevant even for DNA collapse
in cells where the DNA compaction takes place in the presence of interactions with their large
biomolecules in restricted spaces; (ii) AFM experiments are likely to provide the most direct
data for the strength of interaction between semiflexible biomolecules. In these experiments one
of the molecules of interest is anchored onto the surface while force is applied to the end of the
other. The unbinding force can be calculated from the force-extension profiles. These exper-
iments raise the question, namely, what are the adhesive forces between semiflexible polymer
and a surface? We address these questions using theory [12, 27, 28] and simulations for a WLC
model interacting with a solid surface.

In the absence of the surface the morphologies of semiflexible chain (SC) is determined by
thermal fluctuations and an interplay of the chain persistence length $l_p$ and intramolecular
condensation length $l_c = \sqrt{l_p k_B T / u_m}$ where $T$ is the temperature and $u_m$ is the effective in-
tramolecular attractive energy per unit length [20]. In the presence of a surface another length
scale $l_s = \sqrt{l_p k_B T / u_{ads}}$, where $u_{ads}$ is the attractive SC-surface interaction energy per unit length,
plays an essential role in the determination of the structures. The interplay of $l_p$, $l_c$, and $l_s$ will
determine the morphology of the surface-induced structures. It also follows that the response
to applied force measured in terms of force-extension profiles will depend on $l_p$, $l_c$, and $l_s$. In
this paper we explore a range of values of $k_B T$ and $l_s$ to predict the force-extension curves for
semiflexible chains in poor solvent.

II. THEORY

Consider a semiflexible chain interacting with a flat surface with the SC-surface potential
being $U_{ads}$. Force $\mathbf{f} = f \cdot \mathbf{n}_x$ is applied to one end of the chain (Fig. 1). Equilibrium chain
configuration is described using the conditional probability $G(\mathbf{x}_N, \mathbf{x}_1; \mathbf{f})$ of finding the tagged $N^{th}$
monomer at \(\mathbf{x}_N\) given that the monomer \(\mathbf{x}_1\) is anchored at the surface, where \(\mathbf{x}=(r, \mathbf{n})\) includes position vector \(r=(x, y, z)\) and orientation vector \(\mathbf{n}\), respectively. Due to axial symmetry, the free end orientation is specified by the angle \(\theta\) between its tangent vector and the \(x\)-axis and distance from the surface \(x\) (Fig. 1), and the conditional probability \(G(x_N, \theta_N; x_1, \theta_1; f)\) can be used instead of \(G(x_N, \mathbf{x}_1; f)\). In the limit \(L \to \infty\), \(G(x_N, \theta_N; x_1, \theta_1; f)\) is dominated by the ground state \(\psi_0\), so that

\[
G(x_N, \theta_N; x_1, \theta_1; f) \approx \psi_0(x_1, \theta_1; f)\psi_0^\dagger(x_N, \theta_N; f) \exp[-\beta N \epsilon_0]
\]

\(\epsilon_0=E_0/N\) is the equilibrium free energy per monomer and \(\beta=1/k_B T\). If the SC is modeled as a worm-like chain (WLC), then \(\psi_0\) satisfies [22, 27, 28],

\[
-2l_p \gamma \frac{\partial \psi_0}{\partial x} + (1-\gamma^2) \frac{\partial^2 \psi_0}{\partial \gamma^2} - 2\gamma \frac{\partial \psi_0}{\partial \gamma} + \beta l_p \gamma f \psi_0 = \beta(u_{ads}(x) - \epsilon_0)\psi_0
\]

where \(u_{ads} = U_{ads}/N\) is the adsorption potential per monomer and \(\gamma = \cos[\theta]\) (see Fig. 1). To mimic the Lennard-Jones chain-surface attractive interaction used in the Langevin simulations (see Section III), we employ a piece-wise continuous potential, i.e. \(u_{ads} = \infty\) for \(x<0\), \(u_{ads} = -\Delta\) for \(0 \leq x \leq b\) and \(u_{ads} = 0\) for \(x>b\). The monomer density of the adsorbed structures in the absence of force,

\[
n(x) = \int d\theta \psi_0^2(x, \theta)
\]

normalized as \(\int dx n(x)=N\), is calculated by solving Eq. [2] without the last term \(\beta l_p \gamma f \psi_0\).

The perturbative solution of Eq. [2] in the absence of the \(\beta l_p \gamma f\) term, due to Kuznetsov and Sung [27], to the first order in correlation length parameter \(\eta=(4l_p^2/\psi_0)|d^2\psi_0/dx^2|\) is outlined in Appendix A. The solution is

\[
\psi_0(x) = h(b-x)(C_1 \sin \left(\frac{x\sqrt{m_1}}{2l_p}\right) + C_2 \sin \left(\frac{x\sqrt{m_2}}{2l_p}\right) + C_3 \cos \left(\frac{x\sqrt{m_1}}{2l_p}\right) - C_3 \cos \left(\frac{x\sqrt{m_2}}{2l_p}\right)),
\]

\[
\psi_0(x) = C_0 h(x-b) \exp \left(\frac{-x\sqrt{k}}{2l_p}\right)
\]

where \(h(x)\) is the Heaviside function, and \(C_0, C_1, C_2\) and \(C_3\) are constant coefficients; \(m_1, m_2\) and \(k\) are given by

\[
m_{1,2} = \frac{15}{8}(2+\phi_{in})(6+\phi_{in}) \left(1 \mp \sqrt{1 + \frac{16}{5}\frac{\phi_{in}}{6+\phi_{in}}}\right)
\]
\[ k = \frac{15}{8} \left( 2 + \phi_{\text{out}} \right) (6 + \phi_{\text{out}}) \left( -1 + \sqrt{1 + \frac{16}{5} \frac{\phi_{\text{out}}}{6 + \phi_{\text{out}}} \right) \]

and \( \phi_{\text{in}} = \beta (u_{\text{ads}}(x) - \epsilon_0) < 0, \phi_{\text{out}} = -\epsilon_0 > 0 \). By using two continuity requirements and the normalization, we can obtain, respectively, \( \epsilon_0 \) and \( C_0 \) and one of \( C_1, C_2 \) or \( C_3 \). However, the two free constants are to be chosen such that a minimum of \( \epsilon_0 \) is obtained. The minimal free energy corresponding to the ground state for \( x \leq b \) is attained for (i) \( C_1 \neq 0, C_2 = C_3 = 0 \) (i.e. the state with \( m = m_1 \)) and (ii) \( C_2 \neq 0, C_1 = C_3 = 0 \) (\( m = m_2 \)).

Perturbative solution of Eq. (2) ignores variation of \( \psi_0 \) on \( \theta \). Indeed, when \( x \gg l_p, \psi \) becomes nearly isotropic, \( \psi(x, \theta) = \psi(x) \). However, when \( x \sim b < l_p, \psi_0 \) should strongly depend on the angle \( \Theta = \pi/2 + \theta \) between free end of the chain and the surface (Fig. 1). In this range \( -\gamma \partial / \partial x \rightarrow \Theta \partial / \partial x \), \((1 - \gamma^2) \partial^2 / \partial \gamma^2 \rightarrow \partial^2 / \partial \Theta^2 \), \( \gamma \partial / \partial \gamma \rightarrow 0, \gamma f \rightarrow -\Theta f \) and Eq. (2) simplifies, i.e.

\[ \Theta \frac{\partial \psi_0}{\partial x} + \frac{1}{2l_p} \frac{\partial^2 \psi_0}{\partial \Theta^2} - \frac{1}{2} \Theta f \psi_0 = \frac{\beta}{2l_p} (u_{\text{ads}}(x) - \epsilon_0) \psi_0. \]  

The methodology for solving Eq. (6) has been presented by Semenov in Ref. 28 and is outlined in Appendix B. The general solution for \( x > b \) (\( u_{\text{ads}} = 0 \)) is

\[ \psi_0(x, \Theta) = \sum_{n=0,1} C_n x^{1/6-n} \Psi \left( n - \frac{1}{6}, \frac{2}{3}, \frac{2l_p \Theta^3}{9x} \right) \]  

where \( C_0, C_1 \) are constants and the confluent hypergeometric function \( \Psi(\chi, \omega, z) \) is

\[ \Psi(\chi, \omega, z) \equiv \frac{1}{\Gamma(\omega)} \int_0^\infty d\tau \, \tau^{\chi-1}(1+\tau)^{\omega-\chi-1} e^{-\tau z} \]  

where \( \Gamma(\chi) \equiv \int_0^\infty d\tau \tau^{\chi-1} \exp[-\tau] \) is Gamma function. To describe the chain in the range \( x \leq b \), we assume that \( \psi_0 \) is of the form (7) and \( C_0, C_1 \) depend on \( x \). Substituting Eq. (7) into Eq. (6), we obtain:

\[ \frac{dC_0}{dx} = \phi(x) \left( \frac{2l_p}{x} \right)^{1/3} (F_{00} C_0 + F_{01} x^{-1} C_1) \]  

\[ \frac{dC_1}{dx} = \phi(x) \left( \frac{2l_p}{x} \right)^{1/3} (F_{10} x C_0 + F_{11} C_1) \]

where \( F_{nm} = (g_m/\kappa, f_n)/(f_n, f_n), n, m = 0, 1, \) and \( (g_n, g_m) \equiv \int_{-\infty}^\infty d\kappa e^{-\kappa^3/3} f_n(\kappa) g_m(\kappa) \) (see Eq. 22). We solve Eqs. (8) subject to the condition \( \phi(x) = \phi_{\text{in}} \) for \( x < b \) and \( \phi(x) = \phi_{\text{out}} \) for \( x > b \). From the solutions of Eqs. (8) in Appendix B we obtain:

\[ C_{\text{in}}^1(x) = c_2 e^{\frac{3}{2} \sqrt{-Dx^3}} \left( -3 \sqrt{-Dx^3} \right)^{3/2} \Phi \left( \rho + \frac{3}{2}, \frac{5}{2}, -3 \sqrt{-Dx^3} \right) h(b - x) \]  

\[ C_{\text{out}}^1(x) = c_1 e^{\frac{3}{2} \sqrt{-Dx^3}} \Phi \left( \rho, -\frac{1}{2}, 3 \sqrt{-Dx^3} \right) h(x - b) \]
where $\sqrt{-D} = \phi_{out}(2l_p)^{\frac{1}{2}} \sqrt{F_{01}F_{10} - F_{11}F_{00}}$ and $h(x)$ is Heaviside step function. In Eq. (9) the Kummer function $\Phi(k, l, x)$ is defined by $\Phi(k, l, x) = 1 + \sum_{m=1}^{\infty} \frac{(k)_m}{(l)_m} \frac{x^m}{m!}$ with $(k)_0 = 1$, $(k)_1 = k$ and $(k)_m = k(k+1)\ldots(k+m-1)$ [29]. We get $C_0(x)$ by substituting Eqs. (9) for $C_1^{in}$ and $C_1^{out}$ into the second Eq. (8) and $\psi_0(x, \Theta; f)$ can now be obtained by using Eq. (7).

In the presence of pulling force, $\psi_0$ is nearly isotropic, i.e. $\psi_0(x, \theta; f) \approx \psi_0(x; f)$. This allows us to analyze force-extension profiles by employing perturbative treatment outlined above. Solution to Eq. (2) is given by

$$\psi_0(x; f) = \psi_0(x)e^{\frac{1}{2}xfx}$$

where $\psi_0(x)$ is given by Eqs. (4). The average extension as a function of applied force can be computed using

$$\langle x(f) \rangle \equiv \frac{1}{\beta Z(f)} \frac{d}{df} Z(f)$$

where the partition function $Z(f)$ is $Z(f) = \int d\theta_N \int d\theta_1 \int dx_N \int dx_1 G(x_N, \theta_N; x_1, \theta_1; f)$.

The perturbation theory is strictly valid only when the condensation length $l_c \gg l_p$. In practice we find that the first order perturbation theory gives results that are in very good agreement with simulations even when $l_c \sim l_p$. Kuznetsov and Sung also discovered that the perturbation theory is remarkably successful outside the regime of applicability [27].

### III. LANGEVIN DYNAMICS SIMULATIONS

We model a semiflexible chain (SC) by $N=100$ connected beads of bond length $a$ and the contour length $L=100a$. In the absence of $U_{ads}$ and $f=0$, we assume that the dynamics is governed by the overdamped Langevin equation:

$$\xi \frac{d}{dt} x_j = -\frac{\partial U}{\partial x_j} + g_j(t)$$

where $\xi$ is the friction coefficient, $U=U_{chain} = U_{bond} + U_{bend} + U_{LJ}$ is chain internal energy due to bond potential $U_{bond}$, bend potential $U_{bend}$ and interbead interaction potential $U_{LJ}$ (hydrodynamic interactions are ignored). The random force $g_j(t)$ obeys Gaussian statistics,

$$\langle g_j(t) \rangle = 0, \quad \langle g_j(t) g_j(t') \rangle = 6k_BT \xi \delta(t-t')$$
We solve Eq. (12) for each $x_j$ with unit tangent vector $u_j=(x_{j+1}-x_j)/a$, where $j=1,2,\ldots,N$. The stretching potential $U_{\text{bond}}$ is

$$U_{\text{bond}} = \frac{A}{2\sigma^2} \sum_{j=1}^{N-1} (|x_j - x_{j+1}|^2 - \sigma^2),$$

(14)

where $A$ and $\sigma$ are constants, and

$$U_{\text{bend}} = \frac{S}{2} \sum_{j=1}^{N-1} (1 + \cos [\phi_{j,j+1}])^2$$

(15)

where the constant $S$ is a measure of chain stiffness, and $\cos [\phi_{j,j+1}] = (x_{j+1}-x_j)(x_{j-1}-x_j)/\sigma^2$ is the bend angle. The interaction between beads is given by the 12-6 Lennard-Jones potential,

$$U_{\text{LJ}} = B \sum_{i<j} \left[ \left( \frac{\sigma}{\Delta x_{ij}} \right)^{12} - 2 \left( \frac{\sigma}{\Delta x_{ij}} \right)^6 \right]$$

(16)

where $\Delta x_{ij}$ is the distance between beads $i$ and $j$, and $B$ is the magnitude of interaction. $U_{\text{LJ}}$ is an effective interaction that accounts for excluded volume interactions and counterion induced attraction which in DNA is due to screening of the charges. The persistence length of the chain $l_p$ can be roughly estimated by using $l_p=a/(1-\cos \langle \phi_{j,j+1} \rangle)$ where $\langle \phi_{j,j+1} \rangle = (N-1)^{-1} \sum_{j=1}^{N-1} \phi_{j,j+1}$ is the average angle between adjacent beads.

Similar models have been used in previous studies to probe the chain collapse in poor solvents [20, 26]. In the presence of the adsorbing surface the motion of $j$-th bead is governed by Eq. (12) with $U=U_{\text{chain}}+U_{\text{ads}}$, where $U_{\text{ads}}$ is the surface-SC potential,

$$U_{\text{ads}} = \Delta \sum_i \left[ \left( \frac{b}{\Delta x_i} \right)^{12} - 2 \left( \frac{b}{\Delta x_i} \right)^6 \right].$$

(17)

In Eq. (17) $\Delta x_i$ is the bead-surface distance and $\Delta$ and $b$ are, respectively, the depth and range of the attractive forces. We set $B = 1.0$, $\sigma=a=1$ and $b=3a$, and use $A=400B$, $S=30B$, $60B$, $120B$ and $\Delta=1.5B$, $2.0B$, $2.5B$. This makes $U_{\text{LJ}}$, $U_{\text{bond}}$, $U_{\text{bend}}$ and $U_{\text{ads}}$ to scale in units of $\epsilon_h=k_BT$ and $\epsilon_l=\sigma$ is the unit length. The choice $A=400B$ allows for 5 percent of thermal fluctuations in the bond distance and permits us to run simulations with longer time steps without affecting bond relaxation time. The unit of time is $\tau=\xi\sigma^2/\epsilon_h$, where $\xi=44.0$ is the friction coefficient of the chain in water at $T = 300K$. The system of equations (12) is integrated with a step size $\delta t=2\times10^{-2}\tau$ and the total time is $t=N_{\text{tot}}\delta t$ where $N_{\text{tot}}$ is the number of integration steps. We express time either in units of $\tau$ or in terms of $N_{\text{tot}}$. 

IV. RESULTS

A. Surface-induced structural transitions:

It is known that in the absence of the surface SC undergoes a collapse transition when the solvent is poor i.e., when the attractive monomer-monomer interactions dominate (Eq. (16)) so that $l_c > l_p$. The collapse is a result of a competition between intramolecular attraction and bending energy due to chain stiffness. Unlike in flexible polymers, the low energy collapsed conformation is a torus which maximizes intramolecular contacts and minimizes the bending penalty. Before simulating the force-extension curves of adsorbed SC it is necessary to characterize the structures that are obtained when interacting with the surface.

To simulate the low free energy structures that result in the presence of the surface, we first thermalized an extended chain at high temperature $k_B T = 3.0$ for $N_{tot} = 1 \times 10^6$ steps. By gradually decreasing the temperature bulk structures were thermalized for $(1 - 10) \times 10^7$ steps and used in adsorption experiments. Interactions with the attractive surface was switched on at distance $\Delta x = 2b$ away from the bead with shortest $x$ and the SC was adsorbed onto the surface one bead at a time. The structures were allowed to relax for $\sim 1 - 20 \times 10^6$ steps depending on $k_B T$, $S$ and $\Delta$. Progress of adsorption was monitored by analyzing time traces of $U_{LJ}$, $U_{ads}$, $U$, and the radius of gyration $R_g$ of the SC. We generated 500 adsorbed structures at $k_B T = 1.0$, 1.25 and 1.5 for $S = 30B$, 60B, 120B and $\Delta = 1.5B$, 2.0B and 2.5B.

Typical structures are presented in Fig. 2. Geometry of the SC adsorbed onto the surface ranges from partially or fully extended configuration with $l_p / a \approx 18$ to partially structured one-, two- and three-racquet states with $l_p / a \approx 16.0$, 15.5 and 15.0, respectively, to fully ordered toroidal states with $l_p / a \approx 13.5$. Similar structures have been observed in recent studies of collapse of semiflexible chains in the bulk [20, 26]. For the interaction parameters used in our simulations $l_s / l_c \sim o(1)$. Thus, the attractive SC-surface interaction facilitates adsorption of the SC without significantly altering its morphology compared to the bulk case. For $l_s \gg l_c$ the lowest free energy structures are extended.

To compare the kinetics of structure formation on the surface and in the bulk we also simulated collapsed structures in the absence of the adsorbing surface. By analyzing the temporal profiles of $R_g$, $U_{LJ}$ and $l_p$, we found that on average, chains attain structured configurations on a faster timescale when adsorbed on the surface. The search for the ground (toroidal) state is
more efficient when the chain is constrained to evolve on the two-dimensional surface where the SC quickly minimizes its free energy in reduced $d=2$-space by sliding surface motion (lateral diffusion).

### B. Kinetics of surface-induced ordering:

Typically, surface-induced ordered structures form by a two step process $B_0 \rightarrow S_0 \rightarrow S_t$. Starting from the bulk state $B_0$, extended surface transient $S_0$ emerges during the fast first step with the $B_0 \rightarrow S_0$ transition occurring within $N_{tot}=1 - 3 \times 10^6$. In the slower second step $S_0 \rightarrow S_t$, extended transient structures explore the free energy landscape in search of the toroidal state $S_t$ which occurs in about $3 - 20 \times 10^6$ steps depending on $S$, $\Delta$ and temperature. Transition from $S_0$ to $S_t$ is realized via rapid formation of either a surface loop or an intermediate toroid-like motif with larger $R_g$ (smaller winding number) or through a sequence of longer lived racquet states $S_0 \rightarrow S_1 \rightarrow \ldots \rightarrow S_t$, where $S_n$, $n=0,1,2,\ldots$ denotes conformations with number of racquets equal to zero (extended chain) one, two, etc.

The number of “metastable” racquets depends on chain flexibility. We observed configurations with $n=6$ for $S=30B$ and $k_B T=1.25$. Simulated profiles of $R_g$, $U_{LJ}$, $U_{ads}$ and $U$ indicate that evolution from extended to toroidal states follows several pathways. Four out of five simulation runs followed the scheme outlined above. Similar diverse pathways have been observed by Noguchi and Yoshikawa [20] who recorded the lifetime of intermediates species for about $N_{tot}=2.0 \times 10^5$. Our results indicate that attractive surface forces increase the lifetimes of metastable intermediates for stiff chains at low temperature. In few simulation runs toroidal structures were not observed during as many as $20 \times 10^6$ steps. Hence, attractive surface forces facilitate formation of toroidal state primarily when formation of toroid-like intermediate motif is involved.

The dynamics of $R_g$, $U_{LJ}$, $U_{ads}$ and $U$ for the structures in Fig. 2 show that increasingly more ordered states are also energetically favorable (Fig. 3). $R_g$, $U$ and $U_{LJ}$ decrease and $U_{ads}$ increases in the sequence $S_0 \rightarrow S_1 \rightarrow S_2 \rightarrow S_3 \rightarrow S_t$. $R_g$ fluctuates around larger values for extended states. Variations in $U_{LJ}$, $U_{ads}$ and $U$ increasing in the sequence of $S_1 \rightarrow S_2 \rightarrow S_3 \rightarrow S_t$ transitions are due to formation of SC-surface contacts. For the structures in Fig. 2, the formation of $S_1$ at $N_{tot} \approx 2.0 \times 10^6$ is mediated by a surface-loop motif followed by slow sliding motion; $S_2$ forms
early at \( N_{tot} \approx 5.0 \times 10^5 \) and remains unchanged (time dependence of \( R_g \) or \( U_{LJ} \)). The dynamics of \( U_{LJ}, U_{ads} \) and \( U \) show formation of \( S_3 \) via \( S_1 \) at \( N_{tot} \approx 1.0 \times 10^5 \) followed by transition \( S_1 \rightarrow S_3 \) at \( N_{tot} \approx 7.0 \times 10^6 \). Similarly, traces of same quantities for \( S_t \) point at three step transition, \( S_0 \rightarrow S_1 \rightarrow S_3 \rightarrow S_t \) occurring respectively at \( N_{tot} \approx 5.0 \times 10^5, 1.5 \times 10^6 \) and \( 4.0 \times 10^6 \), followed by chain compaction due sliding motion.

In agreement with theoretical arguments \[28\] monomer profiles of stiff chains (\( S=120B, l_p/b \gg 1 \)) are described by the succession of short near-surface loops of length \( \ll l_p/a \) between chain-surface contact and by the combination of short and long loops of the length \( \gg l_p/a \) for \( S=30B \) and \( l_p/b \sim 1 \). Decrease in \( l_p/b \) and temperature favors the formation of chain-surface contacts by enabling more beads to be inside the range of surface forces. This results in the formation of higher ordered states \( S_4, S_5, S_6 \) and \( S_t \). In contrast, at higher temperatures and increased \( \Delta \) and \( S \), surface structures with increased conformational free energy become unstable and unfold into extended configurations (data are not shown). We quantified the geometry of surface structures (Fig. 2) by binning bead-surface distances \( x_j \) into the density histogram \( n(x) \). The monomer density profiles for \( \Delta=1.5B \) and \( k_BT=1.0 \) are compared in Fig. 4 for \( S=70B \) (left) and \( S=50B \) (right panels). Transition from less structured to more structured states is accompanied by an increased ratio of the number of bead-bead to bead-surface contacts. The density distribution \( n(x) \) is single-peaked at \( x=b/2 \) and decays to zero as \( x \rightarrow b \) for extended states and increases its density at \( x \approx b \) in the sequence \( S_1 \rightarrow S_2 \rightarrow S_3 \rightarrow S_t \).

C. Forced unfolding of surface adsorbed structures:

To unfold the surface-ordered structures, these structures were initially allowed to thermalize at \( k_BT=1.0 \) for \( N_{tot}=2 \times 10^6 \). We then anchored the C-terminus of the chain at the surface and pulled its N-terminus with constant force \( f \) via the harmonic spring with the spring constant \( k_{sp}=0.36pNnm^{-1} \) in the direction perpendicular to the surface. Simulation runs were terminated after evolution of chain extension \( x(N_{tot}) \) had reached equilibrium. \( x(N_{tot}) \) of the structures of Fig. 2 are presented in Fig. 5 for \( f=9.75pN, 18.3pN, 24.4pN \) and \( 30.5pN \). Chain extension reaches saturation plateau in the first \( 8 \times 10^7 \) steps as the chain restoring force approaches \( f \). Not unexpectedly, the unfolding threshold force increases as the extent of ordering decreases in the sequence \( S_0 \rightarrow S_1 \rightarrow S_2 \rightarrow S_3 \rightarrow S_t \). At \( f=9.75pN \) only \( S_0 \) unfolds in \( 1.0 \times 10^7 \) steps. When the
force is increased to $f=18.3\,pN$, $S_0$, $S_1$, $S_2$ and $S_3$ unbind from the surface in $3.5\times10^7$, $3.6\times10^7$, $4.0\times10^7$ and $6.0\times10^7$ steps, respectively. At $f=24.4\,pN$ all structures reach the stretched state in $2-4\times10^7$ steps. From the dynamical trajectories of $x$ obtained for $\Delta=1.5B$ and $k_BT=1.0$, we constructed the average extension $\langle x \rangle$ as a function of $f$. In Fig. 6 we compare $\langle x \rangle$ vs $f$ traces for extended, one-racquet, three-racquet and toroidal structures of Fig. 2 ($S=120B$, top panel) and more flexible four-, five- and seven-racquet and toroidal conformations obtained for $S=30B$. Unbinding of surface-anchored structures undergo a highly cooperative all-or-none transition as the unfolding force threshold $f=f_c$ is increased from $7.3-15.8\,pN$ ($S=120B$) to $15.9-17.7\,pN$ ($S=30B$) for more compact racquet and toroidal states.

D. Comparison between theory and simulations:

We analyzed the simulation results for the monomer density and the averaged extension as a function of the pulling force by using perturbative treatment (see Eqs. (3)-(5)) in the entire range of $x<L$. For the proximal limit $x\ll l_p<L$ we use the exact expressions in Eqs. (7) and (9). Density distributions and force-extension profiles for the extended conformation were approximated by choosing the ground state with $m=m_1$ ($m_1<m_2$, see Eq. (5)). The choice $m=m_1$ corresponds to isotropic-like unstructured surface state with no preferred orientation of the chain beads. Histograms of structured two-, three-racquet and toroidal conformations were analyzed with the choice $m=m_2$ corresponding to nematic-like ordered states [27]. To account for the difference between the shape of attractive potential $U_{ads}$ used in the simulations and the theoretical calculation we used, in the actual fit, the rescaled potential depth $\Delta_T=r\Delta_{sim}$ for the same range $b_T=b_{sim}=1$, where $r=(b\Delta_T)^{-1}\int_0^\infty dx u_{ads}(x)$ is the ratio between volume of Lennard-Jones attractive layer and $b\Delta_T$ used in theory. The density profiles $n(x)$ for known values of $b$, $k_BT$ and $\Delta_T$ were fitted to the simulated monomer density histograms and force-extension profiles to obtain parameters $\epsilon_0$ (Eq. (11)) and $l_p$. The theoretical results for the density $n(x)$ and the average extension $\langle x(f) \rangle$ computed from Eqs. (3) and (11), respectively, using these parameters are shown in Figs. 4 and 6.

**Monomer density distributions:** Although the theoretical results for $n(x)$ slightly underestimate the simulated density for structured states for $b<x/a<1.5$ and underestimates it for $x/a>1.6$, the agreement between perturbation theory and simulation data is surprisingly good.
in the range of $x/a \leq b$ (Fig. 4). The agreement between theory and simulations improves for more structured racquet and toroidal conformations. In particular, the theoretical profiles capture the positions of density peaks both inside the layer at $x/a \approx 0.5$ and at the boundary $x/a \approx b$. Although there is some residual density at large $x/a$ due to thermal fluctuations of chain ends, especially for less structured extended and racquet configurations, the ground state dominance approximation is clearly valid. The theoretically estimated conformational free energy per monomer and persistence length for structures $S_0 \rightarrow S_2 \rightarrow S_3 \rightarrow S_t$ of Fig. 4 decrease respectively as $\epsilon_0/k_BT \approx -0.21 \rightarrow -0.23 \rightarrow -0.24 \rightarrow -0.25$ and $l_p/a \approx 11.7 \rightarrow 11.2 \rightarrow 10.4 \rightarrow 10.2$ (for $k_BT=1.0$, left panels), and $\epsilon_0/k_BT \approx -0.23 \rightarrow -0.25 \rightarrow -0.26 \rightarrow -0.27$ and $l_p/a \approx 11.3 \rightarrow 11.0 \rightarrow 10.2 \rightarrow 10.1$ (for $k_BT=1.25$, right panels). Not surprisingly, both $\epsilon_0$ and $l_p$ decrease for the same structures as $k_BT$ is increased because of enhanced chain flexibility. In the proximal region, the exact calculation of $n(s)$ for $0 \leq x/a \leq 0.5$ for the same structure sequence shows a better agreement with the simulated results. The fit parameters are $\epsilon_0/k_BT \approx -0.2 \rightarrow -0.24 \rightarrow -0.25 \rightarrow -0.28$ and $l_p/a \approx 12.3 \rightarrow 11.8 \rightarrow 11.0 \rightarrow 10.8$ for $k_BT=1.0$, and $\epsilon_0/k_BT \approx -0.19 \rightarrow -0.22 \rightarrow -0.24 \rightarrow -0.26$ and $l_p/a \approx 12.0 \rightarrow 11.6 \rightarrow 10.8 \rightarrow 10.6$ for $k_BT=1.25$.

**Force-extension curves:** Apart from small deviations around the unfolding threshold forces for all simulated surface structures, the fit of theoretical curves of the average extension vs pulling force to simulated data points shows excellent agreement between theory and simulations. The theoretical $\langle x(f) \rangle$ curves calculated using perturbation theory follow closely the simulated force-extension profiles both for $S=120B$ and $S=30B$ especially below $(x/L \leq 0.1)$ and above $(x/L \geq 0.9)$. The unbinding threshold forces increase as $7.5pN<10.5pN<12.5pN<16.5pN$ in the sequence $S_0 \rightarrow S_1 \rightarrow S_3 \rightarrow S_t$ ($S=120B$, top panel in Fig. 6) and as $15pN<15.5pN<16.5pN<17.5pN$ in the sequence $S_4 \rightarrow S_5 \rightarrow S_7 \rightarrow S_t$ ($S=30B$, bottom panel in Fig. 6). This implies that more flexible and/or more structured surface chains are harder to unfold. However, “all-or-none” type of simulated unfolding transition shows sharper growth than predicted by the theory. The theoretically estimated conformational free energy per monomer and persistence length for structures $S_0 \rightarrow S_1 \rightarrow S_3 \rightarrow S_t$ decrease respectively as $\epsilon_0/k_BT \approx -0.12 \rightarrow -0.17 \rightarrow -0.20 \rightarrow -0.22$ and $l_p/a \approx 15 \rightarrow 14.5 \rightarrow 14.25 \rightarrow 12.1$ (top panel). For the structures $S_4 \rightarrow S_5 \rightarrow S_7 \rightarrow S_t$, $\epsilon_0$ decreases as $\epsilon_0/k_BT \approx -0.134 \rightarrow -0.136 \rightarrow -0.141 \rightarrow -0.148$ and $l_p/a \approx 8.2 \rightarrow 8.1 \rightarrow 8.0 \rightarrow 7.9$ (bottom panel). Here too, increased chain flexibility decreases $l_p$ and lowers $\epsilon_0$. 

V. CONCLUSIONS

To provide insights into interactions between biomolecules interacting with membranes we have considered collapse and forced-unbinding of semiflexible chains (SC) in the presence of an adsorbing surface. The interaction of SC modeled using WLC, which describes well many of the physical properties of DNA [19], RNA [30], and proteins [31], with a surface into which the SC can adsorb, is studied using theory and simulations. The morphologies of the SC in the presence of an adsorbing potential is described in terms of three length scales, namely, \( l_p \), \( l_s \), and \( l_c \). By restricting ourselves to \( l_c \approx l_s \) we have studied the effect of interaction with the surface on coil-toroidal transition in DNA like chains. The simulations show that the rate of toroid formation is impeded compared to the bulk because interaction with the surface stabilizes many metastable racquet-like structures (Fig. 1). The simulated equilibrium density profiles show that as the range of surface-SC interaction increases and temperature decreases, which leads to a decrease in \( l_p/l_s \), ordered structures form. The peak of \( n(x) \) at \( x \approx b \) (the range of interaction) grows as \( l_p \) decreases. The bimodality in the \( n(x) \) distribution function suggests that the surface-induced toroid formation is a first order transition. The perturbative calculation reproduces qualitatively all the features in the simulated density profiles.

We also considered the peeling and unbinding of adsorbed structures by applying force. These results, which are of direct relevance to AFM experiments [32], show that the forced-unbinding transition is surprisingly highly cooperative. For all structures (racquet-like and toroids) unbinding occurs over a narrow force range. The magnitude of the critical force \( f_c \) for a fixed value of \( T \) and \( l_s \) increases as \( l_p \) decreases. From general considerations we expect that \( f_c \) should be described by a scaling a function \( g(y) \) where \( y = l_s/l_p \) for a fixed \( T \). When \( y < y_c \) (a critical value), then adsorption is not free energetically favored. When \( y > y_c \), then \( f_c \) should increase by an increasing function of \( y \). The increase in \( f_c \) can be achieved either by increasing \( l_s \) for a fixed \( l_p \) or by decreasing \( l_p \) for fixed \( l_s \). Additional work is required to elucidate the nature of the scaling function \( g(y) \). Quite surprisingly, we find that the force-extension profiles can be calculated by using a simple perturbation theory even though the nature of the unbinding transition is abrupt. The present work shows that global properties of force-extension characteristics of adsorbed biomolecules can be nearly quantitatively predicted using the proposed theory.
It is now well established that elastic response of DNA, in the absence of interaction with surfaces, depends sensitively on the nature and concentration of counterions [32, 33]. Our work shows that the force-extension curves in the presence of a surface to which DNA is bound depends not only on \( l_s \) but also on the morphology of the adsorbed structures. The novel prediction that forced unbinding should occur cooperatively by a first-order phase transition can be probed using single molecule experiments.

**APPENDIX A: PERTURBATIVE TREATMENT OF ADSORBED CHAIN STATISTICS**

We expand \( \psi_0 \) (Eq. (1)) in terms of the Legendre polynomials, i.e.

\[
\psi_0(x, \theta) = \sum_{i=0}^{\infty} \psi_i(x) P_i(\cos[\theta])
\]  

(A1)

By using the following equations,

\[
\frac{d}{d\gamma} P_i(\gamma) = -i(i+1) P_i(\gamma) \quad \text{and} \quad P_1(\gamma) P_i(\gamma) = \frac{(i+1)P_{i+1}(\gamma) + iP_{i-1}(\gamma)}{2i+1}
\]  

(A2)

we transform Eq. (2) without term \( \beta l_p \gamma f \psi_0 \) into \((i \geq 0)\)

\[
\frac{i(i+1) + \beta(u_{ads} - \epsilon_0)}{2l_p} \psi_i(x) = -\frac{i}{2i-1} \frac{d\psi_{i-1}(x)}{dx} - \frac{i+1}{2i+3} \frac{d\psi_{i+1}(x)}{dx}
\]  

(A3)

To the first few orders we have:

\[
\psi_0 = \frac{2l_p}{3\beta(u_{ads} - \epsilon_0)} \frac{d\psi_1}{dx} \quad (i = 0),
\]

\[
\psi_1 = -\frac{2l_p}{2 + \beta(u_{ads} - \epsilon_0)} \frac{d\psi_0}{dx} - \frac{4l_p}{5(2 + \beta(u_{ads} - \epsilon_0))} \frac{d\psi_2}{dx} \quad (i = 1),
\]

\[
\psi_2 = -\frac{4l_p}{3(6 + \beta(u_{ads} - \epsilon_0))} \frac{d\psi_1}{dx} - \frac{6l_p}{7(6 + \beta(u_{ads} - \epsilon_0))} \frac{d\psi_3}{dx} \quad (i = 2),
\]
ψ_1 is given by the second Eq. (A4) with the second term determined by ψ_2 which is of the order of 8l_p^3 d^3 ψ_0 / dx^3. Neglecting this order for η ≪ 1 we obtain:

$$\psi_1 \approx -\frac{2l_p}{2 + \beta(u_{ads} - \epsilon_0)} \frac{d\psi_0}{dx}$$  \hspace{1cm} (A5)

Including the second term in the third Eq. (A4) and using Eq. (A5) we obtain the first-order perturbation equation for ψ_1,

$$\psi_1 \approx -\frac{2l_p}{2 + \phi} \frac{d\psi_0}{dx} - \frac{4l_p}{5(2 + \phi)} \frac{d}{dx} \left[ \frac{4l_p}{3(6 + \phi)} \frac{d}{dx} \left( \frac{2l_p}{2 + \phi} \frac{d\psi_0}{dx} \right) \right]$$  \hspace{1cm} (A6)

where $\phi = \beta(u_{ads} - \epsilon_0)$. Substitute Eq. (A6) into the first Eq. (A4) we arrive at the first-order perturbative equation for ψ_0:

$$\frac{64l_p^4}{45\phi(2 + \phi)^2(6 + \phi)} \frac{d^4\psi_0}{dx^4} + \frac{4l_p^2}{3\phi(2 + \phi)} \frac{d^2\psi_0}{dx^2} - \psi_0 = 0$$  \hspace{1cm} (A7)

For the class of potentials considered here, the physical solution of Eq. (A7) that satisfies the boundary conditions,

$$\psi_0(x = 0) = 0, \quad \psi_0(x \to \infty) \to 0, \quad \frac{d^n}{dx^n}\psi_0|_{x \to \infty} \to 0, \quad n = 1, 2, \ldots$$  \hspace{1cm} (A8)

continuity requirements at $x = b$,

$$\psi_0(x \to b - 0) = \psi_0(x \to b + 0), \quad \frac{d}{dx}\psi_0|_{x \to b - 0} = \frac{d}{dx}\psi_0|_{x \to b + 0}$$  \hspace{1cm} (A9)

and normalization condition is given by Eq. (11).

**APPENDIX B: EXACT TREATMENT OF THE CHAIN DISTRIBUTION IN THE PROXIMAL RANGE**

Let us first consider the non-adsorbed chain in the presence of weak potential $u_{ads} \to 0$. Assuming a self-similar distribution, $\psi_0(x, \Theta) = x^\alpha g(\kappa)$ where $\kappa = \Theta(2l_p/x)^{1/3}$, we rewrite Eq. (6) with $u_{ads} = \epsilon_0 = 0$ as an eigenvalue problem for $g(\kappa)$,

$$- \frac{1}{\kappa} \frac{\partial^2 g}{\partial \kappa^2} + \frac{\kappa}{3} \frac{\partial g}{\partial \kappa} = \alpha g$$  \hspace{1cm} (B1)

Upon substitution $z = \kappa^3 / 9$, Eq. (B1) reduces to the following equation:

$$z \frac{d^2 g}{dz^2} + \left( \frac{2}{3} - z \right) \frac{dg}{dz} + \alpha g = 0$$  \hspace{1cm} (B2)
Under condition $g(z \to \infty) \to 0$ the only solution to Eq. (B2) is $g(z) \sim \Psi(-\alpha, 2/3, z)$ where $\Psi(\chi, \omega, z)$ and $\Gamma(\chi)$ are defined in the main text. $\psi(x \to 0, \Theta < 0) \to 0$ defines the spectrum of eigenvalues $\alpha_n = 1/6 - n$, where $n = 0, \pm 1, \pm 2, \ldots$ (see Appendix B in Ref. 28). The requirement that $\psi$ does not have knots is satisfied for $n = 0$ ($\alpha = 1/6$) and $n = 1$ ($\alpha = -5/6$), and the general solution for $u_{ads} = 0$ in the region $x > b$ is given by Eq. (7) of the main text.

To solve Eqs. (8) we substitute $C_0$ from the second equation into the first equation and multiply by $x^{2/3}$. We obtain:

$$x^{4/3} \frac{d^2 C_1}{dx^2} - \frac{2}{3} x^{1/3} \frac{dC_1}{dx} + (\bar{F}_{11} + D x^{2/3}) C_1 = 0$$

where $D = \bar{F}_{00} \bar{F}_{11} - \bar{F}_{01} \bar{F}_{10}$ and $\bar{F}_{nm} = F_{nm}\phi(2l_p)^{1/3}$, $n, m = 0, 1$. Substituting $y = x^{1/3}$ into Eq. (B3) and multiplying it by $y^2$, we get:

$$y^2 \frac{d^2 C_1}{dy^2} - 2y \frac{dC_1}{dy} + y^2 (9\bar{F}_{11} + 9 Dy^2) C_1 = 0$$

(B4)

Using $z = y^2$ allows us to rewrite Eq. (B4) as

$$\gamma_2 z \frac{d^2 C_1}{dz^2} + \beta_1 \frac{dC_1}{dz} + (\gamma_0 z + \beta_0) C_1 = 0$$

(B5)

where $\gamma_0 = 9D$, $\beta_0 = 9\bar{F}_{11}$, $\beta_1 = -4$ and $\gamma_2 = 4$. The general solution of Eq. (B5) is given by

$$C_1(x) = e^{\frac{3}{2} \sqrt{-D} x^2} [c_1 \Phi(\rho, -\frac{1}{2}, -3\sqrt{-D} x^2) + c_2 (-3\sqrt{-D} x^2)^{\frac{3}{2}} \Phi(\rho + \frac{3}{2}, \frac{5}{2}, -3\sqrt{-D} x^2)]$$

(B6)

where $c_1, c_2$ are constants and $\rho = (3\bar{F}_{11} - 2\sqrt{-D})/4\sqrt{-D}$. In Eq. (B6) $\Phi(k, l, x)$ is the Kummer series defined in the text. In the range $0 \leq x \leq b$, $\psi_1(x, \Theta = 0)$ diverges as $x \to 0$. To avoid this divergence we require that $C_1(x = 0) = 0$. This is satisfied when $c_1 = 0$. To insure that $C_1(x) \to 0$ as $x \to \infty$ for $x > b$, we set $c_2 = 0$. Substituting $\phi = \phi_{in}$ and $\phi = \phi_{out}$ into solutions for $0 \leq x \leq b$ and $x > b$ and using formulas $\Phi(k, l, x) = e^x \Phi(l - k, l, x)$, $\frac{d^m}{dx^m} \Phi(k, l, x) = \frac{(k)_m}{(l)_m} \Phi(k + m, l + m, x)$ we obtain Eqs. (9).

FIGURE CAPTIONS

Figure 1: Schematic of a semiflexible chain (blue) adsorbed on the surface (yellow). The free end \((\mathbf{r}, \mathbf{n})\) makes an angle \(\theta = \arccos \frac{\mathbf{n} \cdot \mathbf{n}_x}{|\mathbf{n}| \cdot |\mathbf{n}_x|}\) with the direction \(\mathbf{n}_x\) of the pulling force \(f = f \mathbf{n}_x\). For clarity, the chain is shown as extended which is realized only when the SC-surface interaction is strong. The interaction between the monomers of the chain and the surface is attractive in the range \(0 \leq x \leq b\) where \(x\) is the distance perpendicular to the surface. The strength of the interaction is \(\Delta\). In the Langevin simulations we replace the square well potential by the Lennard-Jones potential (Eq. (17)).

Figure 2: Top view of the typical structures (blue) adsorbed on the surface (yellow) for \(S = 120B\), \(\Delta = 1.5B\) and \(k_B T = 1.0\). Extended, one-racquet, two-racquet, three-racquet and toroidal structures are obtained in a single trajectory that is terminated at \(t = 4 \times 10^{-5}\tau\). The equilibrium structure under these conditions is the toroid.

Figure 3: Dependence of radius of gyration \(R_g/a\) (top left), intramolecular attractive interaction \(U_{LJ}\) (Eq. (16)), surface potential \(U_{ads}\) (Eq. (17)), and the internal energy \(U (=U_{bend} + U_{bend} + U_{LJ})\) displayed as functions of time, measured in units of \(\tau\). The five curves in each panel correspond to extended (black), one-racquet (red), two-racquet (green), three-racquet (blue) and toroidal (magenta) structures of Fig. 2.

Figure 4: The average monomer density profiles \(n(x)\) as a function of \(x/b\) for \(\Delta = 1.5B\) and \(k_B T = 1.0\) for extended, two-racquet, three-racquet and toroidal states. The left panel is for \(S = 70B\) and the results for \(S = 50B\) are shown on the right. Solid lines and dotted lines represent the results obtained using perturbative and exact theory, respectively.

Figure 5: Dynamics of extension \(x\) (in units of \(a\)) for a few trajectories at different values of \(f\) applied to the chain ends of structures shown in Fig. 2. Time \(t\) is expressed in units of \(\tau\). The colors correspond to the caption in Fig. 3. The values of \(f\) are displayed in the panels.

Figure 6: The averaged reduced extension \(\langle x \rangle/L\) as a function of constant force \(f\) simulated for \(\Delta = 1.5B\) and \(k_B T = 1.0\) for structures in Fig. 2 (\(S = 120B\), top). The bottom panel shows force-extension profiles for four-, five-, seven-racquet and toroidal configurations obtained for \(S = 30B\) (bottom panel). Data points for extended (four-racquet), one-racquet (five-racquet),
three-racquet (seven-racquet) and toroidal structures are given by red, green, blue and black circles, respectively. Theoretical curves for these structures are given respectively by solid, dotted, dashed and dot-dashed lines.
