ABSTRACT

One of the most frequent kidney pathologies encountered in daily practice is represented by the presence of renal cysts. Most of them are asymptomatic and are found accidentally during periodical check-ups because they don’t have clinical signs until they grow and compress the surrounding organs. We have reviewed the current data regarding this pathology, in order to underline the risk of malignant transformation and its impact on the patient’s life. It is estimated that the prevalence rate of renal cysts in the general population is approximately 10% and it increases with age. Imaging investigations, such as contrast tomography or magnetic resonance imaging, are essential for establishing the cysts characteristics, especially when

RéSUMÉ

Le rôle de la classification Bosniak dans l’évaluation des masses kystiques rénales et dans le protocole thérapeutique

Une des pathologies rénales les plus fréquentes dans la pratique quotidienne est la présence de kystes rénaux. La plupart d’entre eux sont asymptomatiques et se retrouvent accidentellement lors des examens périodiques, car ils ne présentent aucun signe clinique tant qu’ils ne se développent pas et ne compriment pas les organes environnants. Nous avons passé en revue les données actuelles concernant cette pathologie, afin de souligner le risque de transformation maligne et son impact sur la vie du patient. On estime que le taux de
ultrasonography raises the suspicion of a modified renal cyst, as well as in guiding the therapeutical protocol. The Bosniak classification is based on contrast tomography scans and has allowed the standardization of the kidney cysts, considering their characteristics. More attention should be given to Bosniak IIF and III cystic renal masses, which contain thickened walls and more septa, but no enhanced nodules/soft tissue components, because more than half of these cysts can have a malignant component.

Keywords: renal cysts, Bosniak classification, malignant transformation.

Introduction

Cystic kidney lesions are usually asymptomatic, being diagnosed accidentally during ultrasonography. Renal cysts become symptomatic when they increase in size and compress the surrounding organs. Therefore, these patients can present symptoms such as lumbar or flank pain, especially during physical activity, a palpable lumbar mass that can mimic other renal or retroperitoneal tumors. It may also compress the urinary pathway, leading to hydronephrosis and to the atrophy of the renal parenchyma. Quite often, the patients with multiple renal cysts will eventually lose the function of that kidney, due to the compression exerted by the cysts on the renal parenchyma. Before establishing the diagnosis of a destroyed kidney and the indication of nephrectomy, it is mandatory to perform renal scintigraphy in order to assess the renal function. These patients will unfortunately develop chronic renal failure that may impose dialysis. Other important complications that can appear as a result of the urinary stasis are hydroelectrolytic imbalances that may further lead to arrhythmias. Like any other renal masses, renal cysts, depending on their size and compressive effect on the surrounding tissues, can also determine persistent high blood pressure. Other rare complications are dyspnea, neurological deficits, venous syndrome. According to literature, renal cysts are one of the most common findings during imaging investigations, their appearance being related to risk factors such as smoking, male sex, nephrolithiasis or aging. We have reviewed the current data about renal cysts and the risk of malignant transformation using the PubMed database in order to underline the importance of this pathology.

The Bosniak Classification

The Bosniak classification was developed in 1986 and since then it has been used to evaluate renal cystic masses and to guide the therapeutical management. The Bosniak criteria may also be useful for ultrasound and magnetic resonance imaging evaluation. Both imaging techniques have similar results in terms of cystic renal masses assessment. According to the Bosniak criteria, kidney cysts can be classified as follows:

Type I: implies the presence of a simple kidney cyst, which represents the majority of kidney cysts, usually detected during imaging investigations for other pathologies. They have homogeneous content with fluid attenuation (0–20 UH), regular contour and a clear interface between the fluid content and the renal parenchyma, without the presence of intracystic septa or calcifications. More attention should be given to Bosniak IIF and III cystic renal masses, which contain thickened walls and more septa, but no enhanced nodules/soft tissue components, because more than half of these cysts can have a malignant component.

Type II: compared to type I kidney cysts, this type of kidney cysts is characterized by the presence of thin septa, usually with a thickness less than 1 mm, as well as linear, parietal or septal calcifications.

Type III: this type was included in 1993, because there was a group of lesions that could not be classified as Bosniak III and due to the fact that more complications could appear for this type of cysts compared to the type II Bosniak cyst. These lesions may prove difficult to assess, due to the fact that they present multiple thin or slightly thickened septa, minimally

Mots-clés: kystes rénaux, classification bosniaque, transformation maligne.
thickened walls and regular contour. Kidney hyperdense cysts are included in his category.22,23

Type III: presents irregular and thick septa, wall thickening and contrast enhancement, with or without calcifications. They can appear as multilocular, hemorrhagic or infected cyst. These cysts may prove challenging when establishing their benign or malignant character.24

Type IV: this category is characterized by the presence of a malignant cystic mass, which can present imaging characteristics similar to those encountered in a type III kidney cyst. Unlike the type III cyst, the type IV cyst has a solid component, that can be observed near the walls or near the intracystic septa. These renal masses must be considered as being renal carcinoma, with clear surgery indication, because they are malign in 95-100% of the cases.25,26

Even if a simple asymptomatic Bosniak type I cyst is found, a regular follow-up must be performed at least every twelve months. In our clinic, we have encountered patients who have presented themselves seeking medical advice and treatment for a simple renal cyst, the type IV cyst has a solid component, that can be observed near the walls or near the intracystic septa. These renal masses must be considered as being renal carcinoma, with clear surgery indication, because they are malign in 95-100% of the cases.25,26

Several years later, at a routine check-up, it was discovered that the cyst had changed its characteristics: from a simple Bosniak type I renal cyst it had transformed into a cyst with irregular and thick septations and with a solid component, these changes being suggestive for a Bosniak IV renal cyst. Therefore, the surgical indication was certain. We have performed radical nephrectomy and the histopathological examination had confirmed its malignant character. This is why regular follow-ups are necessary after discovering the presence of a renal cyst.

Another study conducted by Bata et al has showed that Bosniak type III cysts are more likely to be malignant than it was initially expected. The study was made on 19 patients with radiological diagnosis of Bosniak type III cysts. Nephron sparing surgery was performed in 13 cases and the remaining six patients have undergone total nephrectomy. The authors have reported that only 3 patients presented hematuria before the diagnosis was established and that the other patients have complained of flank pain or were asymptomatic. Histopathological analysis confirmed that 16 out of 19 lesions were conventional clear cell renal cell carcinomas (84%).27

The Bosniak classification was created in 1986 in order to ensure a more accurate diagnosis, as well as to ease up the therapeutical protocol. The magnetic resonance imaging technique has an excellent soft-tissue resolution, that can bring a more sensitive information about the solid component renal cyst compared to CT examination.28 Older studies have shown a surprising variability in the percentage of malignant Bosniak III cysts (31%-100%), these numbers being based on small series studies that used older CT technology. Other six studies (each one included more than 30 renal cystic masses) have found that approximately 65% of the Bosniak III lesions were malignant. Over all, all recent studies show that more than 50% of the Bosniak III cysts have a malignant component. However, these previous studies have serious limitations because of the older type of CT used.

Pathological studies have revealed that the most frequent type of malignant renal tumors is usually conventional clear cell renal carcinoma. It is estimated that only 4-15% of all renal cell carcinomas is represented by cystic growth pattern. Several studies have shown that there is a higher rate of renal carcinoma in the presence of a precursor cystic lesion.

Recent studies revealed that the use of intravenous sonographic contrast agent may allow for a better detection of a complex cystic lesions, even in cases of very thin septa (hair-like), with an accuracy superior to CT. The disadvantage of this procedure is the cost of the contrast agent, that is higher than the iodinated contrast agent, and low reproducibility of the method.

Conclusions

The Bosniak classification of renal cystic masses has allowed the standardization and the management of renal cystic lesions. This classification can also be used for the magnetic resonance imaging technique and not only for the CT examination. Ultrasonography remains an excellent method used for the screening of renal cystic lesions. More attention should be paid to Bosniak IIF or III lesions based on magnetic resonance imaging, which contains thickened walls and more septa, but no enhanced nodules/soft tissue components, because more than half of them can have a malignant component.
