*Mycoplasma*, which was used to create the first “s“ythetic life”, has been an important species in the emerging field, synthetic biology. However, essential genes, an important concept of synthetic biology, for both *M. mycoides* and *M. capricolum*, as well as 14 other *Mycoplasma* with available genomes, are still unknown. We have developed a gene essentiality prediction algorithm that incorporates information of biased gene strand distribution, homologous search and codon adaptation index. The algorithm, which achieved an accuracy of 80.8% and 78.9% in self-consistence and cross-validation tests, respectively, predicted 5880 essential genes in the 16 *Mycoplasma* genomes. The intersection set of essential genes in available *Mycoplasma* genomes consists of 153 core essential genes. The predicted essential genes (available from pDEG, tubic.tju.edu.cn/pdeg) and the proposed algorithm can be helpful for studying minimal *Mycoplasma* genomes as well as essential genes in other genomes.

The year 2010 saw the creation of the first artificial self-replicating bacterial cells. In this famous work, Venter’s group designed, synthesized and assembled JCVI-syn1.0, a 1.08 Mb *Mycoplasma mycoides* genome, which was then transplanted into a *M. capricolum* recipient cell. These efforts resulted in the creation of new *M. mycoides* cells, whose genetic materials only contain the synthetic chromosomes. This is a technical milestone in the emerging field, synthetic biology, because conceptually, it means a synthetic life can be designed and made.

An important concept of synthetic biology is the minimal genome, which contains all essential genes of an organism. The minimal genome can serve as a chassis in which interchangeable elements are inserted to create organisms with desirable traits. *Mycoplasma* has been an important species for synthetic biology, mainly because of their small genome sizes. The first genome-scale gene essentiality screen was performed in a *Mycoplasma* genome. However, the essential genes for both *M. mycoides* and *M. capricolum*, as well as those for 14 other *Mycoplasma* with available genomes are not known. The goal of the current study was to develop a novel and reliable algorithm to predict essential genes in the 16 *Mycoplasma* genomes.

Identification of essential genes *in silico* is important and necessary, not only because their experimental determination is highly labor-intensive and time-consuming, but also because the speed for genome sequencing far outpaces that of the genome-wide gene essentiality studies. Although experimental techniques in identifying essential genes have been dramatically improved, genome-wide gene essentiality data are only available in 15 bacterial genomes. In contrast, the number of available genomes has reached 1000, and the projects of sequencing 4000 more bacterial genomes are underway. With the increasing ability for genome sequencing, *in silico* prediction of essential genes will be more and more important.

Various algorithms have been proposed to predict essential genes. Most algorithms are based on various genomic features, which include connectivity in protein-protein interaction network, fluctuation in mRNA expression, evolutionary rate, phylogenetic conservation, GC content, codon adaptation index (CAI), predicted sub-cellular localization and codon usages. Because bacterial essential gene products comprise attractive drug targets for developing antibiotics, some studies are aimed at identifying essential genes that could serve as drug targets. These studies mainly rely on homologous search against available essential genes, for instance, through homologous searches against DEG (database of essential genes), based on the notion that those homologous to known essential genes are likely to be essential also. These bacterial pathogens include: *Pseudomonas aeruginosa*, *Burkholderia pseudomallei*, *H. pylori*, *Aeromonas hydrophila*, *Neisseria gonorrhoeae*, *Acromonas hydrophila* and *Wolbachia*. Very recently, Duffield and coworkers, by using a modified down-selectoin computational tool, predicted 52 essential genes that are conserved in 7 or more genomes in DEG, and 7 of the 8 genes that were experimentally validated in *Yersinia pseudotuberculosis* were found to be essential.

Essential genes have been known to be biasedly distributed in leading and lagging strands in *E. coli* and *B. subtilis*. We then confirmed this phenomenon in 10 genomes in which gene essentiality screens had been...
performed\textsuperscript{22}. However, the information of the biased essential gene distribution has not been effectively integrated into the gene essentiality prediction programs. With the availability of DoriC\textsuperscript{24}, the database that contains replication origins for almost all bacterial genomes, such information (gene distribution in leading and lagging strands), if can be effectively used, will be helpful for the essential gene prediction for most bacterial genomes.

We developed an algorithm that integrates the information of biased distribution of essential genes in leading and lagging strands, in addition to homologous search and CAI values. The algorithm, which is simple and reliable, achieved an accuracy of 80.8\% in predicting essential genes in \textit{M. pulmonis} genome (self-consistence test), and achieved an accuracy of 78.9\% and 78.1\% in predicting those in \textit{S. aureus} and \textit{Bacillus subtilis} genomes, respectively (cross validation tests). Second, we then predicted 5880 essential genes in 16 \textit{Mycoplasma} genomes. The detailed information of the genes is organized into a Database of predicted Essential Genes (pDEG) (http://tubic.tju.edu.cn/pdeg). The intersection set of essential genes in 18 \textit{Mycoplasma} genomes (5880 predicted in the 16 \textit{Mycoplasma} genomes, 379 and 310 experimentally determined in \textit{M. genitalium} and \textit{M. pulmonis}, respectively), consists of 153 core essential genes. The proposed algorithm and the prediction results will be helpful for studying essential genes in \textit{Mycoplasma} as well as in other genomes. In particular, it is helpful for designing various \textit{Mycoplasma} chassis used in synthetic biology.

## Results

### Training procedure and the self-consistence test

The training set included 379 and 310 essential genes for \textit{M. genitalium G37} (\textit{M. gen}) and \textit{M. pulmonis} UAB CTIP (\textit{M. pul}), respectively. The training procedure could be performed in one of the two manners: essential genes of \textit{M. pul} are predicted based on those of \textit{M. gen}; or conversely, essential genes of \textit{M. gen} are predicted based on those of \textit{M. pul}. Since the average size of the 16 \textit{Mycoplasma} genomes is about 1 Mb (see Table 1), the \textit{M. gen} genome did not seem to be a suitable representative, because it has the smallest genome size (0.58 Mb). Therefore, we chose to train the parameters based on the first manner, i.e., essential genes of \textit{M. pul} (genome size about 1 Mb), were predicted based on the experimentally determined ones of \textit{M. gen}. The highest prediction accuracy achieved in the training procedure represents the self-consistence test accuracy that the present algorithm can reach. The parameters obtained following the training procedure can then be used to predict essential genes in the 16 \textit{Mycoplasma} genomes.

Comparing the prediction with essential genes identified experimentally in the \textit{M. pul} genome, parameters were determined such that the prediction accuracy reached the best value. The detailed training procedure is described in Fig. 1. We intended to keep the sensitivity \(S_n\) being roughly equal to the specificity \(S_p\) (Fig. 2a). The corresponding ROC curve is shown in Fig. 2b, where the AUC (Area Under the Curve) value was 0.812. The detailed prediction accuracy in terms of leading and lagging strands is listed in Table 2. Overall, the accuracy was 80.8\% (\(S_n = 0.78\) and \(S_p = 0.83\)), which may be considered as the highest self-consistence test accuracy that the present algorithm can reach.

### Cross-validation test

In addition to the self-consistence tests, the algorithm should also be evaluated by an independent data set. That is, once the parameters are determined, they should be tested by using a genome whose essential genes are experimentally determined, but \textit{M. gen} and \textit{M. pul} genomes should be excluded. However, so far \textit{M. gen} and \textit{M. pul} have been the only 2 genomes in the \textit{Mycoplasma} family that have genome wide gene essentiality studies performed. Therefore, instead of using the information of essential genes of a third \textit{Mycoplasma} genome, which is unavailable, we chose to use two bacterial genomes closely related to the two \textit{Mycoplasma} genomes, \textit{Bacillus subtilis} str. 168 and \textit{Staphylococcus aureus} N315, whose essential genes were identified experimentally\textsuperscript{25-27}. Using the parameters in the training procedure of the algorithm, we predicted the essential genes for \textit{B. subtilis} str. 168 and \textit{S. aureus} N315. We find that instead of merely using the information of the 379 essential genes in the \textit{M. gen} genome, the prediction accuracy can be improved using the combined set of the 379 and 310 essential genes in genomes of \textit{M. gen} and \textit{M. pul}, respectively. The prediction results are listed in Table 3. The average AUC value equals to \((0.813 + 0.778)/2 = 0.796\). The average prediction accuracy (78.1\% + 78.9\%)/2 = 78.5\% may be deemed as the cross-validation test accuracy.

detailed information for each of the predicted essential gene is described in a database of predicted essential genes (pDEG), which is accessible from the website: http://tubic.tju.edu.cn/pdeg/. The database pDEG is organized with the same form as DEG. In pDEG, the detailed information of all the predicted essential genes can be obtained, including their names, functions, DNA and protein sequences and COG codes. If a predicted essential gene codes for an enzyme, the EC number and the KEGG linkage describing the involved metabolic pathway are also provided. Users can search for a predicted essential gene by their functions and names, and can also browse and download all the records in pDEG.

Core essential genes for the Mycoplasma family. The phylogenetic tree of the 18 Mycoplasma genomes was drawn based on the 16S rRNA (Fig. 3), where the abbreviations of 18 bacteria are shown in Table 1. We then obtained the intersection set of genes and essential genes based on reciprocal homolog searches between genomes. For example, the number of intersection genes between the genomes of M. mycoides and M. capricolum was 679. The number of overall intersection genes among the 18 Mycoplasma genomes was 191. Similarly, the numbers of intersection essential genes between two genomes or two genome clusters are shown in Fig. 3b. Note that the essential genes of the M. genitalium and M. pulmonis genome are identified experimentally, whereas the essential genes of remaining 16 bacterial genomes are predicted in the present study.

The intersection set of the essential genes in the 18 Mycoplasma genomes (5880 predicted in the 16 Mycoplasma genomes, 379 and 310 experimentally determined in M. genitalium and M. pulmonis, respectively) consists of 153 genes, which are called core essential genes for the Mycoplasma family. The core essential genes likely encode functions that are absolutely required for the survival of Mycoplasma, and their homologues in other bacteria likely have critical functions as well. Detailed information of the 153 core essential genes is available from pDEG.

**Discussion**

Essential genes are those indispensable for the survival of an organism under certain conditions, and the essential-gene concept is especially important for the burgeoning field, synthetic biology. A goal in synthetic-biology field is to develop the cellular chassis, which is commercially important for the burgeoning field, synthetic biology. A goal in synthetic biology is to develop the cellular chassis, which is commercially important for the...
core essential genes. For Mycoplasma species, pan essential genes are the combined essential gene set, while core essential genes are the intersection set of essential genes among Mycoplasma species. Based on the current dataset, the number of Mycoplasma pan essential genes is 6569 (5880 predicted, 379 and 310 experimentally determined in M. genitalium and M. pulmonis, respectively). However, we hypothesize that although the number of pan essential genes will continue to increase with more Mycoplasma genomes, the number of core essential genes (153) will largely remain the same. The core essential genes are likely needed for all Mycoplasma genomes and are likely all needed for the Mycoplasma chassis.

Indeed, the core essential genes are generally functionally important, and are involved in critical cellular processes. Based on COG functional classification, core essential genes, compared to non-core essential and non-essential genes, had a higher proportion of genes involved in information storage and processing (Fig. 4a, and most of the core ones (55%) are involved in translation, ribosomal structure, transcription and replication (Fig. 4b). For example, they include most genes coding for 30S, 50S ribosomal proteins and aminoacyl-tRNA synthetases. They include those involved in replication, such as replication initiation protein ( dnaA ), replication DNA helicase ( dnaB ), DNA gyrase subunit A ( gyrA ) and subunit B ( gyrB ), DNA ligase ( ligA ), DNA polymerase III subunit-related proteins ( dnaX, polC ) and DNA primase ( dnaG ). They include genes of 4 protein synthesis elongation factors G, P, Ts and Tu ( fusA, efp, tsf and tuf ) and 2 translation initiation factors IF-2 ( infB ) and IF-3 ( infC ), and transcription related genes, such as DNA-directed RNA polymerase subunit alpha ( rpoA ) and beta ( rpoB ) and RNA polymerase sigma factor RpoD ( rpoD ). They also include almost all subunits of F0F1 ATP synthase ( atpA, atpB, atpD, atpE and atpG ) and many enzymes involved in energy production and metabolism. For details, refer to http://tubic.tju.edu.cn/pdeg/core/.

It is noteworthy that some core essential genes do not have clearly defined functions. For instance, MG_423 encodes a hypothetical protein (accession number NP_073094) in the M. genitalium genome. Blast searches suggested that this gene likely encodes ribonuclease J, which plays a key in mRNA degradation. Being a core essential gene prioritizes this gene to be further functionally characterized.

In summary, we here have predicted essential genes of the 16 Mycoplasma genomes currently available in GenBank, based on experimentally identified essential genes of the M. genitalium and M. pulmonis genomes. The algorithm is simple and effective. The cross-validation test shows that the sensitivity $S_n$ and the specificity $S_p$ of the algorithm are all roughly equal to 80%. This accuracy means that about 80% of the essential genes in the Mycoplasma genomes under study are correctly predicted as essential; likewise, about 80% of the non-essential genes in these genomes are correctly predicted as non-essential. The high accuracy achieved is mainly due to the homologous mapping among evolutionally closely related bacteria, together with other information including biased distribution of essential genes in leading and lagging strands and CAI values. Mycoplasma has been an important species in the field of synthetic biology. The prediction results and the proposed algorithm can be useful in studying the minimal genomes of Mycoplasma, and in gene essentiality studies for other genomes. In particular, it is helpful for designing various Mycoplasma chassis used in synthetic biology.
Methods

The genomic RefSeq protein sequences for all the 18 Mycoplasma genomes were downloaded from the NCBI website (ftp://ftp.ncbi.nih.gov/genomes/Bacteria). The alignment program BLAST+ was downloaded from the same website (version Blast-2.2.23+, ftp://ftp.ncbi.nih.gov/blast). There are 379 and 310 experimentally determined essential genes for M. genitalium G3736 and M. pulmonis UAB CTIP37, respectively. It is noteworthy that definition of essential genes depends on certain experimental conditions, such as in rich growth medium. In addition, synthetic lethal (lethality due to inactivation of more than 1 gene) is not considered in single gene knockout experiments. The detailed information for each of the 18 Mycoplasma genomes is listed in Table 1.

Following parameters were used in the present study to assess the performance of the algorithm.

\[
S_n = \frac{TP}{TP + FN} \tag{1}
\]

\[
S_p = \frac{TN}{TN + FP} \tag{2}
\]

\[
A = \frac{S_n + S_p}{2} \tag{3}
\]

\[
\epsilon = \begin{cases} 
1, & \text{if } E = 0, \\
\frac{\log_{10}E}{\log_{10}E_{\text{min}}}, & \text{if } E \neq 0 
\end{cases} \tag{4}
\]

where \(TP, FN, FP\) and \(TN\) denote true positives, false negatives, false positives and true negatives, respectively. The sensitivity \(S_n\) represents the proportion of essential genes that have been correctly predicted as essential. The specificity \(S_p\) represents the proportion of non-essential genes that have been correctly predicted as non-essential.

The positive prediction rate \(S_n\) represents the percentage of essential genes over the predicted ones. The accuracy \(A\) is the average of the sensitivity and specificity.

The prediction is partially based on the alignment of protein primary sequences to be predicted against those from closely related organisms in DEG, using the program Blastp. For each query protein sequence, we define

\[
\epsilon = \begin{cases} 
1, & \text{if } E = 0, \\
\frac{\log_{10}E}{\log_{10}E_{\text{min}}}, & \text{if } E \neq 0 
\end{cases} \tag{5}
\]

Figure 4 | Functional classification of genes in the M. genitalium genome based on COG. (A) COG classification of core-essential, non-core-essential and non-essential genes in M. genitalium. (B) Distribution of COG classification of the 153 core-essential genes.
where $E$ is the expectation value of the best scoring alignment in Blastp (with default parameters), and $E_{\text{ref}}$ is the smallest $E$ value other than 0 of all genes from the 18 *Mycoplasma* genomes.

The prediction is also based on the strand-bias of essential genes\textsuperscript{17}. We define

$$b = \begin{cases} 1 + \beta_1, & \text{if the gene to be predicted is at the leading strand;} \\ 1 + \beta_2, & \text{if the gene to be predicted is at the lagging strand,} \end{cases}$$

where $b$ is a real number and $\beta_1, \beta_2 \in [-1, 1]$. The replication origin and terminus are determined based on the DorIC database\textsuperscript{26}.

Finally, the prediction is also partially based on the CAI value of a gene to be predicted\textsuperscript{13,14,16}. The CAI values were calculated using the CodonW software (http://codonw.sourceforge.net). We define

$$c = 1 + \gamma \times \frac{\text{CAI} - \overline{\text{CAI}}}{\overline{\text{CAI}}},$$

where $c$ is a real number and $\gamma \in [0, 1]$. Accordingly, we define the prediction parameter $s$ by

$$s = e \times b \times c.$$ 

Using an iterative procedure (Fig. 1), the parameters $\beta$ and $\gamma$ were determined based on the training set. For each gene to be predicted we calculate the set of parameters ($e$, $b$, $c$), and finally the prediction parameter $s$. We further look for a threshold $s_0$ such that if $s > s_0$, the gene is predicted to be essential, otherwise, if $s \leq s_0$, the gene is predicted to be non-essential. Detailed prediction results are available from the website http://tubic.tju.edu.cn/pdeg/, and programs are available upon request.

---

**Acknowledgements**

We would like to thank Prof. CT Zhang for invaluable assistance and inspiring discussion. The present work was supported in part by a fund (176412) from Wayne State University to R.R.Z., and by the National Natural Science Foundation of China (Grant No. 90408028).

**Author contributions**

Conceived and designed the experiments: RRZ. Performed the experiments: YL. Analyzed the data: RRZ and YL. Wrote the paper: RRZ.
