(Dated: September 7, 2018)

Homoeptaxial diamond layers doped with boron in the 10²⁰ − 10²¹ cm⁻³ range are shown to be type II superconductors with sharp transitions (∼ 0.2 K) at temperatures increasing from 0 to 2.1 K with boron contents. The critical concentration for the onset of superconductivity is about 5 − 7 10²⁰ cm⁻³, close to the metal-insulator transition. The H – T phase diagram has been obtained from transport and a.c. susceptibility measurements down to 300 mK. These results bring new quantitative constraints on the theoretical models proposed for superconductivity in diamond.

PACS numbers: 74.25.Op, 74.63.c, 73.61.Cw

Table I: Sample characteristics: thickness (t), gas phase ratio ((B/C)gas), boron concentration (nB) and critical temperatures (Tc) for the studied diamond epilayers films

| Sample | t (µm) | (B/C)gas (ppm) | nB (10²⁰ cm⁻³) | Tc (K) |
|--------|--------|---------------|----------------|--------|
| 1      | 3.0    | 1615          | 3.6            | ≤ 0.05 |
| 2      | 3.0    | 1730          | 9              | 0.9    |
| 3      | 3.0    | 1845          | 10             | 1.2    |
| 4      | 2.0    | 2200          | 11.5           | 1.4    |
| 5      | 0.15   | 2800          | 19             | 2.1    |

Type II superconductivity has been recently reported for heavily boron-doped polycrystalline diamond prepared either as bulk [1] or thin film samples [2], providing a new interesting system for the study of superconductivity in doped semiconductors. Based on the great bonding strength of the valence band states and on their strong coupling to the carbon lattice phonons, various theoretical studies [3, 4] have stressed the similarity between diamond and the recently discovered MgB₂ system which shows a surprisingly high Tc value on the order of 40 K. Those calculations lead to Tc values in the 0.2 to 25 K range (depending on the boron content) but ignore the boron impurity band [3, 4]. An alternative theoretical approach [3] stresses out the fact that the boron concentration range where superconductivity has been observed is close to the Anderson-Mott metal-insulator transition and suggests an electron correlation driven extended s-wave superconductivity in the boron impurity band.

The open questions of the nature of the metal-insulator transition (MIT) in diamond and of its correlation with superconductivity are of fundamental interest and provide ample motivation for this first investigation of the dependence of the superconducting transition temperature on the doping boron concentration. In this letter, we report on magnetic and transport experiments on a set of high quality single crystalline epiyayers doped in the relevant 10²⁰ − 10²¹ cm⁻³ range. We show that Tc rapidly rises above some critical concentration ∼ 5 − 7 10²⁰ cm⁻³ reaching ∼ 2 K for nB = 19 10²⁰ cm⁻³ (see Table 1).

001-oriented type Ib diamond substrates were first exposed to a pure hydrogen plasma. Methane (4%) was subsequently introduced and a 0.5µm-thick buffer layer of non-intentionally doped material was deposited at 820°C by the microwave plasma-assisted decomposition (MPCVD) of the gas mixture at a total pressure of 30 Torr. Finally, diborane was introduced in the vertical silica wall reactor with boron to carbon concentration ratios in the gas phase ((B/C)gas) ranging from 1500 to 3000 ppm. With a typical growth rate of 0.9µm/hr these deposition conditions led to 0.1 to 4µm-thick p⁺−type diamond layers. Secondary Ion Mass Spectroscopy (SIMS) depth profiles of ¹¹B⁺, ¹²C− and ¹²B¹²C− ions were measured using a Cs⁺ primary ion beam in a Cameca IMS 4f apparatus. As shown in Fig.1 for samples 2, 4 and 5, these profiles were found to be flat or with a slow decrease toward the buffer layer. The boron atomic densities nB shown both in Fig.1 and Table 1 were derived from a quantitative comparison to a SIMS profile measured under the same conditions in a B−implanted diamond crystal with a known peak boron concentration of 2.4 10²⁰ cm⁻³. For thin enough samples, the profile yielded also the residual doping level in the buffer layer, around 10¹⁸ cm⁻³. Moreover, the single crystal and epitaxial character of the MPCVD layers was checked by high resolution X-ray diffraction, yielding shifted narrow lines with smaller linewidths at half maximum than for the Ib substrate (typically 10 arcsec for the 004 Bragg spot of the epilayer, instead of 13 arcsec for the sub-
from ac-susceptibility measurements (port measurements [8].

The chemical composition [6], structural [7, 8] and optical [6, 8, 9] characteristics of these layers at room temperature are well documented and have been reviewed recently, together with some preliminary transport measurements [8].

The superconducting temperatures have been deduced from ac-susceptibility measurements (χac). The films have been placed on top of miniature coils and Tc has been obtained by detecting the change in the self induction of the coils induced by the superconducting transitions. For fully screening samples, we observed a 4% drop of the induction L (∼1 mH). Small ac-excitation fields (ω ∼ 99 kHz and hac ∼ a few mG) have been applied perpendicularly to the films. Four Au/Ti electrodes were deposited on top of the film with the highest Tc for magneto-transport measurements. A very small current (∼1 nA) corresponding to a current density on the order of 10⁻³ Acm⁻² has been used to avoid flux flow dissipation. A standard lock-in technique at 17 Hz was used to measure the temperature dependencies of the sample resistance at fixed magnetic fields. The measurements were performed down to 50 mK (χac) and 300mK (transport) and the magnetic field was applied perpendicularly to the doped plane of the sample.

The critical temperatures (see Table 1) reported in Fig.2 have been deduced from the onset of the diamagnetic signal (see inset of Fig.2). The susceptibility has been rescaled to −1 in the superconducting state and a N ∼ 0.9 demagnetization coefficient has been used (the values of Tc do not depend on this choice). This choice for N leads to a dissipation peak on the order of 0.2−0.3 as expected for the non linear regime. This is consistent with the observation of a slight increase of the width of the transition for increasing hac values. As shown in the inset of Fig.2 (and Fig.3), the transitions are very sharp (with a width ∼ 0.2 K) allowing an accurate determination of Tc and stressing out the high quality of our samples. In comparison, the polycrystalline samples measured in previous reports presented a much larger resistivity transition width, ∼1.7 K in [1] and ∼2.6 K in [2].

No transition was observed down to 50 mK for the film with n_B = 3.6 10²⁰ cm⁻³. For higher boron concentrations, Tc increases rapidly with doping above some critical concentration ∼ 5−7 10²⁰ cm⁻³ reaching 2.1 K for n_B = 19 10²⁰ at.cm⁻³. The dependance of Tc with doping extrapolates towards the data recently obtained by [1]. On the contrary, our Tc value for n_B ∼ 10²¹ cm⁻³ (∼1 K) is much lower than the one recently reported by [2] (∼4−7 K). Our data suggests that these authors have largely underestimated the boron concentration of their polycrystalline samples. They deduced this concentration from Hall measurements which are known to give results that deviate significantly from the actual boron concentration in p⁺−type diamond [7]. It is also worth noticing that we observed superconducting transitions with Tc on the order of 1 K for boron contents ∼ 0.5at.% whereas recent calculations of the electron-phonon coupling led to much smaller Tc values for these doping levels [1, 4, 5].

The influence of an external field on the superconducting transition is displayed in Fig.3. As shown in panel a, the transition is shifted towards lower temperatures as the magnetic field is increased. The transition width re-
an accurate measurements, some care should be taken in order to define for larger fields. In the absence of thermodynamic means relatively small up to \( \sim 1 \) T and rapidly increases for larger fields. In the absence of thermodynamic measurements, some care should be taken in order to define an accurate \( H_{c2} \) line. This line has been defined from the classical \( R/R_n = 90\% \) criterion (where \( R_n \) is the normal state resistance). As shown in Fig.4, the corresponding \( H_{c2}(T) \) line can be well described by the classical WHH theory [10]. We hence get \( H_{c2}(0) \sim 1.4 \) T corresponding to a coherence length \( \xi_0 = \sqrt{\Phi_0/2\pi H_{c2}(0)} \sim 150 \) Å for \( n_B = 19 \times 10^{20} \) cm\(^{-3} \) (\( \Phi_0 \) being the flux quantum). We have also reported on Fig.4 the line corresponding to \( R/R_n = 10\% \) which gives an indication for the width of the transition, pointing out that the transition curves rapidly increase for \( H > 1 \) T. For sample 2, this line has been deduced from the shift of the diamagnetic response with increasing fields. In this case, the rapid broadening of the transition is the hallmark of a small critical current density \( (J_c) \) again emphasizing the high quality of our films. Indeed, in the non linear regime, the susceptibility is directly related to \( J_c d/\hbar \) \( (d \) is a characteristic length scale on the order of the sample thickness) and \( J_c \approx \hbar d/\xi_0 \sim 1 \) A cm\(^{-2} \) for \( \chi' \sim -0.4 \). In this case, no saturation was observed down to 200 mK, indicating some deviation from the classical WHH behaviour. Note that for both samples the slope \( |dH_{c2}/dT|_{T\rightarrow0} \sim 1 \) T/K, which is almost 2 times smaller than the value reported by Ekimov et al. [1].

We obtained an almost temperature-independent normal-state resistivity on the order of 0.5 mΩ cm for \( n_B = 19 \times 10^{20} \) cm\(^{-3} \) suggesting that our samples are close to the metal-insulator transition. On the basis of the criterion first proposed by Mott [11] for metal-non metal transitions, which in its final form \( (N_r^{1/3} a_H = 0.26, \) where \( a_H \) is the Bohr radius) has been verified in a wide variety of condensed media [12], the critical concentration in \( p \)-type diamond is expected to be around \( N_r = 1-2 \times 10^{20} \) cm\(^{-3} \). Limitations to this approach arise from the discrepancies in the values proposed in the literature for the acceptor Bohr radius \( a_H \), in line with other inconsistencies about the valence band parameters of diamond. From an experimental point of view, extrapolations [14]...
of the Pearson-Bardeen model \[15\] have led to \(N_c\) values ranging from 1.5 to 3.0 \(10^{20}\) cm\(^{-3}\), while different transport measurements have prompted other authors to propose that \(N_c \sim 7 \times 10^{20}\) cm\(^{-3}\) \[10\]. It is worth noticing that those values have been deduced from room temperature measurements. To the best of our knowledge, the only low temperature estimate \((N_c \sim 40 \times 10^{20}\) cm\(^{-3}\)) has been proposed by Tschepe et al. \[13\] on the basis of a scaling analysis of the electrical conductivity. However, the absolute conductivity values of their implanted samples are much lower than ours despite larger boron concentrations.

The proximity of a MIT in this system, makes it very favorable for the observation of quantum fluctuation effects. The strength of these fluctuations can be quantified through the quantity \(Q_u = R_{eff}/R_Q\) where \(R_Q = h/e^2 \sim 4.1\) k\(\Omega\) is the quantum resistance and \(R_{eff} = \rho N/s\) \((s\) is a relevant length scale for these fluctuations \[18\]). Taking \(\rho N \sim 5 \times 10^{-4}\) \(\Omega\)\ cm and \(s \sim \xi(0) \sim 150\) \(\AA\), we obtain a large \(Q_u\) ratio \(\sim 0.1\) indicating that quantum effects may be important in this system. These quantum fluctuations may give rise to the melting of the flux line lattice and thus lead to the rapid broadening of the resistive transitions observed at low \(T\) and large \(H\). Another indication for such quantum effects, is the almost temperature-independent mixed state resistivity above 1.2 T as previously observed in other systems with similar \(Q_u\) values \[10, 20\].

To conclude, we were able to prepare highly homogeneous and well characterized boron-doped diamond films in the \(10^{20} - 10^{21}\) cm\(^{-3}\) range where superconductivity occurs. The value of the critical concentration for the onset of superconductivity is on the order of \(5 - 7 \times 10^{20}\) cm\(^{-3}\). Boron-doped diamond is an ideal system to study the occurrence of superconductivity close to the metal-insulator transition. As a consequence, quantum effects are expected to play a significant role as suggested by the large quantum resistance ratio \(Q_u \sim 0.1\).

We are grateful to F. Pruvost who grew some of the diamond layers and to Dr L. Ortega (Cristallographie, CNRS, Grenoble) for the X-ray diffraction experiments.
