INTRODUCTION

Obesity is associated with increased mean arterial pressure (MAP) and renal sympathetic nerve activity (RSNA). Accumulating evidence suggests these changes are due to greater circulating concentrations of the adipokine leptin (Burke et al., 2013; Lim et al., 2013) which strongly correlate with RSNA and MAP in animal models of obesity (Prior et al., 2010; Burke et al., 2013). Consumption of a high fat diet (HFD) augments MAP and heart rate (HR) within the first few days of the diet, prior to any change in bodyweight (Burke et al., 2013). However, levels of circulating leptin are proportional to adiposity (Considine et al., 1996) and only begin to increase by the end of the first week of a HFD (Armitage et al., 2012). Thus, rapid changes in cardiovascular parameters suggest that a separate, leptin independent mechanism initiates the pressor response to a HFD. Plasma insulin concentrations increase within hours of meal consumption (Cummings et al., 2001) and are greater in both obese animals and humans (Bagdade et al., 1967; Lim et al., 2013) as well as patients with essential hypertension (Sobotka et al., 2011). Importantly, insulin is known to signal at the arcuate nucleus of the hypothalamus, the same nucleus at which a multitude of peripheral signals, including leptin, act to regulate energy and haemodynamic homeostasis (Benoit et al., 2004). Central administration of insulin attenuates food intake (Air et al., 2002) and augments sympathetic output (Muntzel et al., 1994). We have previously shown that insulin signaling is one of the factors responsible for the development of obesity related hypertension which is later maintained by slowly rising circulating leptin concentrations (Lim et al., 2013).

The association between dyslipidaemia and obesity is important given several lipid species are associated with a number of cardiovascular risk factors (Siri-Tarino et al., 2010). In addition, a single high-fat meal has been shown to reduce endothelial-dependent vasodilation up to 4 h post consumption in healthy normotensive individuals (Vogel et al., 1997). It has been suggested that endothelial-mediated vasodilatory mechanisms are impaired by triacylglycerides (TG) and free fatty acids (Doi et al., 1998; Lundman et al., 2001). Thus, it is possible that diet-induced changes in lipid profiles may play an early role in the development of obesity related hypertension. Lipid profiles have received scant attention in the fat-fed rabbit model of obesity related hypertension and only after several weeks of fat feeding (Eppel et al., 2013).

Although the association between obesity and hypertension is well-known, the underlying mechanism remains elusive. Previously, we have shown that 3 week fat feeding in rabbits produces greater visceral adiposity, hypertension, tachycardia and elevated renal sympathetic nerve activity (RSNA) compared to rabbits on a normal diet. Because hyperinsulinaemia, hyperleptinaemia, and dyslipidaemia are independent cardiovascular risk factors associated with hypertension we compared plasma insulin, leptin, and lipid profiles in male New Zealand White rabbits fed a normal fat diet (NFD 4.3% fat, n = 11) or high fat diet (HFD 13.4% fat, n = 13) at days 1, 2, 3 and weeks 1, 2, 3 of the diet. Plasma concentrations of diacylglyceride (DG), triacylglyceride (TG), ceramide and cholesteryl esters (CE) were obtained after analysis by liquid chromatography mass spectrometry. Plasma insulin and glucose increased within the first 3 days of the diet in HFD rabbits (P < 0.05) and remained elevated at week 1 (P < 0.05). Blood pressure and heart rate (HR) followed a similar pattern. By contrast, in both groups, plasma leptin levels remained unchanged during the first few days (P > 0.05), increasing by week 3 in fat fed animals alone (P < 0.05). Concentrations of total DG, TG, CE, and Ceramide at week 3 did not differ between groups (P > 0.05). Our data show plasma insulin increases rapidly following consumption of a HFD and suggests that it may play a role in the rapid rise of blood pressure. Dyslipidaemia does not appear to contribute to the hypertension in this animal model.

Keywords: insulin, leptin, plasma lipids, obesity, hypertension
The contribution of dyslipidaemia to the progression of disease is well-documented. Increased circulating ceramide concentrations are known to increase in obesity and are inversely correlated with insulin resistance (Haus et al., 2009). In addition, circulating levels of TG and cholesterol esters (CE) are also elevated in obesity and have been shown to affect fasting glucose and insulin sensitivity (Sassolas et al., 1981; Cameron et al., 2008). In the present study the effect of HFD consumption on plasma insulin, leptin, and plasma lipid profiles was assessed in order to elucidate the contribution of each to the rapid rise in MAP observed within the first week of the diet.

MATERIALS AND METHODS

ANIMALS AND DIETS

Experiments were approved by the Alfred Medical Research Education Precinct Animal Ethics Committee and conducted in accordance with the Australian Code of Practice for Scientific Use of Animals. Experiments were conducted in 24 conscious male New Zealand White rabbits (2.76–2.90 kg). Rabbits were housed in individual cages with a telemetry blood pressure receiver (model RLA 1020, Data Sciences International, St. Paul, MN, U.S.A) fitted to the door, under controlled light (6:00–18:00) and temperature (22°C ± 2°C) conditions. Rabbits were initially fed a restricted (150 g daily) normal-fat diet (NFD; 4.3 % total fat, 2.63 kcal/g, Specialty Feeds, Glen Forest, Australia) but after baseline recordings were randomized into two dietary groups and given free access to either a NFD or a high-fat diet (HFD; 13.4 % total fat, 3.34 kcal/g, Specialty Feeds) for 3 weeks. Daily food intake was determined by weighing the contents of the food hopper daily as well as weighing the food added.

EXPERIMENTAL PROCEDURES

A subset of rabbits underwent a preliminary operation under isoflurane anesthesia (3–4% in 1L/min oxygen; Abbot, Botany, NSW, Australia) following induction with propofol (10 mg/kg, Fresenius Kabi, Pymble, NSW, Australia). A radiotelemetry transmitter (model TA11PA-D70, Data Sciences) and catheter was implanted in the aorta via a small branch of the left iliac artery. Carprofen (3 mg/kg, Pfizer, Noth Ryde, NSW, Australia) was given before and 24 h after surgery for analgesia. After 1 week recovery, baseline MAP and HR were measured in the laboratory both by telemetry and by a catheter in the central ear artery. The telemetry signal was calibrated to the ear artery signal and this adjustment was applied to MAP measured in the home cage to minimize the possibility of drift of the signal with time. Baseline home cage MAP and HR were recorded for 1–2 days before rabbits were allocated to a group to receive either NFD or HFD. Home cage measurements were made continuously over 2 weeks.

PLASMA COLLECTION AND ANALYSIS

In order to avoid the effects of recent food consumption, animals were fasted for 4 h before blood samples were collected. Blood was collected before and on days 1, 2, 3, 7, 14, and 21 following the start of the HFD. Small samples of blood were used to measure blood glucose concentrations (Optium Xceed, Abbott, Doncaster, Victoria, Australia). Arterial blood (4 ml) was drawn into vacuum sealed cylinders containing K3EDTA (Vacuette Premium, Greiner bio-one, Wemmel, Belgium) and spun at 4°C for 10 min at 3000 RPM. Plasma aliquots (100 µl) were snap frozen in liquid nitrogen and stored at −80°C until use. Plasma lipid species were extracted into chloroform/methanol and quantified using high performance liquid chromatography-tandem mass spectrometry (Weir et al., 2013). Lipid species identified were diacylglycerides (DG), TG, ceramides (Cer), and CE. Total lipids within each class were calculated from the sum of the individual species. Plasma insulin and leptin concentrations were assessed using an ultrasensitive insulin ELISA kit (Crystal Chem, Chicago, USA) with rabbit insulin standard and a radio immunnoassay multispecies kit (LINCO Research, St Charles, MO, USA), respectively.

DATA ANALYSIS

MAP and HR, derived from the pressure pulse, were digitized online at 500 Hz using an analog-to-digital data acquisition card (National Instruments 6024E, Austin, Texas, USA) and averaged over 2 s. MAP and HR were collected continuously over each 24 h period and averaged over one hourly intervals. Data were analyzed by split-plot repeated measures ANOVA allowing for between and within animal comparisons using excel version 2010 (Microsoft). MAP and HR were analyzed by repeated measures analysis of variance that allowed for within-animal contrasts. Data collected at a single time point were analyzed using a One-Way ANOVA. Bonferroni corrections were used to control for Type 1 error. A two sided probability of $P < 0.05$ was considered significant. For all statistics shown we refer to the main effect as a subscript, e.g., $P_{baseline}$ pertains to comparisons between groups made prior to the consumption of either diet, $P_{group}$, refers to comparisons between HFD and NFD-fed rabbits during dietary intervention; $P_{diet}$ refers to contrasts between baseline and dietary intervention within both NFD and HFD groups, $P_{time}$, refers to comparisons within each group made between baseline and week 3 time points, $P_{dietxtime}$ pertains to the interaction between diet and time.

RESULTS

EFFEKT OF 3 WEEK FAT FEEDING ON PLASMA INSULIN, GLUCOSE AND LEPTIN, FOOD INTAKE AND HAEMODYNAMICS

Baseline plasma insulin concentrations were not different between the dietary groups and averaged 0.46 ± 0.03 ng/ml ($P_{baseline} > 0.05$; Figure 1, Table 1). A 50% increase from baseline in plasma insulin was observed in both NFD and HFD rabbits over the first 2 days of the diet ($P_{diet} < 0.05$ for both groups; Figure 1). A further increase in plasma insulin concentrations on day 3 resulted in 65% greater insulin concentrations in HFD compared with NFD rabbits at both day 3 and week 1 time points ($P_{group} < 0.05$; Figure 1). By week 2, insulin concentrations in HFD rabbits had decreased to those observed in NFD rabbits ($P_{group} > 0.05$; Figure 1). Plasma glucose concentrations at baseline were not different between the dietary groups and averaged 5.5 ± 0.12 mmol/L ($P_{baseline} > 0.05$; Figure 1, Table 1). Plasma glucose concentrations followed a similar pattern to insulin, rising on days 1 and 2 of the diet in both NFD and HFD rabbits ($P_{diet} < 0.05$ for both groups; Figure 1). However, HFD rabbits exhibited a 59% greater increase in plasma glucose concentrations than controls ($P_{group} < 0.05$). By week 2, glucose concentrations...

returned to levels observed in NFD rabbits (P<sub>group</sub> > 0.05; Figure 1). By contrast, plasma leptin concentrations, which were averaged 0.91 ± 0.13 ng/ml at baseline (P<sub>baseline</sub> > 0.05; Figure 1, Table 1), remained unchanged over the first 3 days of the diet in both dietary group (P<sub>diet</sub> > 0.05; Figure 1). However, plasma leptin concentrations in HFD-fed rabbits increased on week 1 of the diet compared with baseline (P<sub>diet</sub> > 0.05; Figure 1) and were 60% greater than controls by the end of week 3 (P<sub>group</sub> < 0.05; Figure 1). Food intake was similar in both groups with rabbits consuming 47–51% more food on the first day of both diets (P<sub>diet</sub> < 0.05). Intake in both groups gradually diminished to baseline levels after the first week (Figure 1). HR also increased rapidly on the first day after the start of the HFD to a level 12% greater than baseline (P<sub>diet</sub> < 0.001; Figure 1). HR remained elevated for the first week but had returned to control levels by week 2 (P<sub>diet</sub> > 0.05). By contrast, MAP increased from baseline levels by the 3rd day of the HFD (P<sub>diet</sub> < 0.05; Figure 1) and remained 7–8% elevated at 1–2 weeks (P<sub>diet</sub> < 0.01; Figure 1). Both MAP and HR in HFD fed rabbits were markedly higher over the 2 weeks of measurements than those fed a NFD (P<sub>group</sub> < 0.001; Figure 1).

CE, cholesteryl esters; NFD, normal fat diet; HFD, high fat diet.

EFFECT OF HFD FEEDING ON PLASMA LIPID PROFILES

After 3 weeks of diet, total plasma DG, TG, Cer, and CE concentrations were not different between the dietary groups (\( P_{\text{group}} > 0.05; \) Figure 2). Specific DG, TG, and CE species did not change over the 3-week diet in either dietary group (\( P_{\text{time}} > 0.05 \) for both NFD and HFD, Tables 2–5). By contrast, plasma Cer 16:0, 20:0, and 22:0 concentrations increased in HFD-fed rabbits over the 3 week period (\( P_{\text{time}} > 0.05; \) Table 2) yet this was unlikely due to the consumption of the HFD (\( P_{\text{diet}} > 0.05; \) Table 2) as the overall interaction between diet and time did not reach statistical significance (\( P_{\text{diet} \times \text{time}} > 0.05; \) Table 2). Individual cholesteryl ester species at week 3 were not different between the dietary groups (\( P_{\text{group}} > 0.05; \) Table 3). Similarly, DG (\( P_{\text{group}} > 0.05; \) Table 4) and TG (\( P_{\text{group}} > 0.05; \) Table 5) lipid species were not different between the dietary groups.

DISCUSSION

The main findings of the present study were that alongside elevations in blood pressure and HR, plasma glucose and insulin concentrations were increased within the first 3 days of a HFD, remaining elevated for the first week of the diet and returning to control levels thereafter. Notably, circulating leptin concentrations were unaltered by a HFD at day 3 but were markedly increased by week 3 whilst in the same time period, no evidence of dyslipidaemia was found. Together, these data suggest hyperinsulinemia rapidly develops after the commencement of a HFD and is a likely mechanism by which haemodynamics and sympathetic tone may change rapidly in the fat-fed rabbit model of obesity related hypertension.

A considerable body of evidence suggests insulin acts centrally to increase both blood pressure and sympathetic tone (Landsberg, 1996; Straznicky et al., 2010; Ward et al., 2011; Lim et al., 2013). There is a strong association between obesity, hyperinsulinemia and, at a later stage, insulin resistance (Weyer et al., 2001; Yuan et al., 2001). Of note is the apparent delay between the engagement of sympathetic nerve activity in obesity and the development of insulin resistance (Flaa et al., 2008) suggesting sympathetic overactivity may occur in response to very early changes in plasma insulin. Indeed central injections of insulin into the paraventricular nucleus of the hypothalamus produce large increases in lumbar sympathetic nerve activity (Ward et al., 2011). In the present study we observed a near two-fold increase in plasma glucose and insulin concentrations within 3 days of starting the HFD. Importantly, increases in MAP and HR in HFD-fed rabbits also began in the first few days of consumption as do increases in RSNA (Armitage et al., 2012; Burke et al., 2013) suggesting that circulating insulin may be involved in augmenting MAP early in the diet. In support of this are the findings...

DG, diacylglycerides; NFD, normal fat diet; HFD, high fat diet.

that central administration of an insulin antagonist attenuated MAP after 1 week of a HFD (Lim et al., 2013). It is important to note that in the present study, plasma leptin concentrations in HFD-fed rabbits remained unchanged over the first 3 days of the diet but had increased by week 3. These results help explain our previous findings that central administration of a leptin antagonist to HFD-fed rabbits failed to elicit a reduction in either haemodynamic or sympathetic parameters at week 1 of the diet but produced large sympathoinhibitory and depressor responses at week 3 (Lim et al., 2013). Combined, these observations imply plasma insulin is involved in the remodeling of sympathetic tone within the first few days of consuming a HFD whilst leptin acts as a sympatheoexcitatory signal later on in the diet, presumably once adiposity is increased. As both plasma glucose and insulin concentrations normalized by week 2 of the diet, the present observations point to sympathetic output preceding insulin resistance. Moreover, the apparent lack of effect of central administration of insulin on RSNA has been observed by others (Ward et al., 2011) and may in part be due to the direct effect of insulin on baroreflex gain (Pricher et al., 2008).

The present study also sought to establish the presence of dyslipidemia in our obese rabbit model and any subsequent contribution to the development of hypertension observed in these animals. In humans, dyslipidemia is a prominent feature of metabolic syndrome (Bays, 2009) and often appears in conjunction with hypertension (Nguyen et al., 2008). An example of the consequences of dyslipidemia can be found in greater total plasma ceramide concentrations which are known to occur in obesity whilst specific ceramide species are strongly associated with insulin resistance (Haus et al., 2009). In the present study, plasma concentrations of 4 lipid classes (Cer, CE, DG, and TG) were unchanged after 3 weeks of HFD. Our findings are in agreement with those made by Eppel and colleagues who observed no change in total plasma cholesteryl, and total plasma TG in rabbits fed a HFD for 9 weeks (Eppel et al., 2013) and suggests large changes in lipid profiles may take longer to develop in the rabbit model (Hamilton and Carroll, 1976). However, given the rapid haemodynamic and hormonal responses to dietary fat content, we expected to find changes in the expression of individual lipid species which would have been indicative of altered lipid metabolism. It is likely that our study was not powered to detect minute perturbations in the expression of specific plasma lipid species, contributing to our findings that plasma lipid profiles are unchanged by a diet high in fat. However, given that other parameters found in plasma, including insulin and leptin, can be measured accurately, our design is unlikely to be a confounding factor.
thus, our findings discount dyslipidemia as a likely mechanism by which hypertension occurs during 3 weeks of a HFD.

In conclusion, our findings demonstrate plasma insulin is a likely mechanism by which rapid increases in MAP occur over the first few days of consumption of a HFD. In addition, dyslipidaemia does not appear to develop after 3 weeks of fat feeding suggesting plasma lipid profiles do not play a role in the genesis of hypertension in our animal model but may contribute to the
