Abstract: Imaging atmospheric Cherenkov telescope (IACT) arrays such as VERITAS are used for ground-based very high-energy gamma-ray astronomy. This is accomplished by the detection and analysis of the Cherenkov light produced by gamma-ray-initiated atmospheric air showers. IACTs also detect the Cherenkov light emitted by individual muons. Identification of these muons is useful because their Cherenkov light can be used to calibrate the telescopes. Muons create characteristic annular patterns in the cameras of IACTs, which may be identified using parametrization algorithms. One such algorithm, the Hough transform, has been successfully used to identify muons in VERITAS data. Details of this technique are presented here, including results regarding its effectiveness.

Keywords: icrc2013, VERITAS, Hough, transform, muons.

1 VERITAS

VERITAS (shown in figure 1) is an array of four 12m imaging atmospheric Cherenkov telescopes (IACTs) located at the base of Mount Hopkins in southern Arizona. Very high energy gamma rays interact with nuclei in the atmosphere, producing extensive air showers. The particles in the air showers move faster than the speed of light in air, emitting Cherenkov light. This light is collected and focused with large segmented reflectors onto arrays of light sensitive photomultiplier tubes (PMTs) called cameras. The PMTs produce signals that are proportional to the amount of light detected. These signals are converted into digital information, providing images of the air showers. The directions of the incident gamma rays are determined by the geometry of the images. The energies of the gamma rays are related to the geometry of the images and the amount of light detected. In order to measure the energies of the incident gamma rays, the intensity of the signals recorded must be related to the amount of light detected. This relationship is a poorly constrained parameter in the energy calibration of IACTs. Muons can be used as calibrated light sources to better determine this relationship.

2 Muons

Muons emit Cherenkov light in a cone at a nearly constant angle as they propagate through the lower atmosphere. This creates annular patterns in IACT cameras, with radii determined by the Cherenkov angles of the muons. Muons propagating parallel to the optical axis (on-axis muons) that hit the center of the reflector (impact parameter \(b = 0\)) appear as complete rings with azimuthally symmetric light distributions in the cameras. On-axis muons with \(b \neq 0\) but less than the radius of the reflector \(R\) appear as complete rings with azimuthally dependent light distributions in the cameras as shown in figures 2 and 3. Distant on-axis muons with \(b > R\) appear as incomplete rings (arcs) in the cameras. Muons propagating at angles not parallel to the optical axis appear as rings or arcs with centers offset from the center of the cameras. The amount of light produced by muons with known Cherenkov angles and impact parameters is well understood. Therefore, muons can be used to calibrate the energy measurements of the telescopes. Since muons produce characteristic patterns, these images can be parametrized using feature finding algorithms such as the Hough transform.

3 Hough transform

The Hough transform is an algorithm used for parametrizing assumed shapes (in this case, circles) in digital images. This algorithm converts the problem of iteratively fitting a circle in image space into a problem of finding the best parameters for a circle in a parameter space. Each parameter must have a limited range and resolution defined by the user. Therefore, each pixel in a digital image is intersected by a finite number of circular parametrizations. Each of the circles describes a point in a 3D parameter space intersected by a finite number of circular parametrizations. The locations of the centers of each PMT in the VERITAS cameras were used as the location of the centers of the circles, and the radii of the circles consisted of values from 3 PMT diameters to 11 PMT diameters, incremented by a third of a PMT diameter. This choice of parametrizations resulted in 12475 distinct circles being used to generate the lookup table. This lookup table was used to perform the Hough transform on VERITAS events.

4 Muon identification parameters

Figure 4 shows the pixel intensity patterns (left) and 2D parameter space projections in the \((x, y)\) plane (right) for a muon event (top) and a non-muon event (bottom). The red, green and blue circles superimposed over the pixel patterns correspond to the coordinates of the bins of the accumulator array with the highest, second highest and third highest values. For the muon event, the three best parametrizations trace the pixel pattern quite well and a sharp peak can be seen in parameter space projection. For the non-muon event, the three best parametrizations differ significantly in center locations and radii and a less peaked distribution can be seen in the parameter space projection. These features were used to motivate the first two muon identification parameters described below:

The AP parameter: the value of the bin of the accumulator array with the most votes divided by the average non-zero bin value. Specifically:

\[
AP = \frac{\text{Largest bin value}}{\text{Sum of all bin values}} \times \frac{\text{Number of non-zero bins}}{1000}
\]

The AP parameter can be thought of as a measure of the strength or signal to noise ratio of the best parametrization of the event. Since muon events produce sharp peaks in the accumulator array, they should have large AP values.

The TD parameter: the sum of the distances in the parameter space between the three best parametrizations of the event. Specifically, if \((x_1, y_1, r_1)\), \((x_2, y_2, r_2)\) and \((x_3, y_3, r_3)\) represent the best, second best and third best parametrizations of the event, then:

\[
TD = D_{12} + D_{13} + D_{23}
\]

where,

\[
D_{12} = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + (r_1 - r_2)^2}
\]

\[
D_{13} = \sqrt{(x_1 - x_3)^2 + (y_1 - y_3)^2 + (r_1 - r_3)^2}
\]

\[
D_{23} = \sqrt{(x_2 - x_3)^2 + (y_2 - y_3)^2 + (r_2 - r_3)^2}
\]

The TD parameter can be thought of as a measure of the unanimity of the parametrizations, or the continuity of the parameter space distribution. Since the three best parametrizations are similar for muon events, these events should have small TD values.

The Npix parameter: the number of pixels with non-zero values after standard image processing is applied.

\[\text{Index: 2170} \quad \text{Npix: 51} \quad \text{AP: 10.11} \quad \text{TD: 80.275}\]

\[\text{Index: 2188} \quad \text{Npix: 31} \quad \text{AP: 4.17} \quad \text{TD: 424.270}\]
5 Cuts and results

In order to test the effectiveness of the parameters described in the previous section for muon identification, 22774 events from the same run were visually inspected and categorized. These events were labeled muons, non-muons or ambiguous. Events with fewer than 10 hit pixels were not categorized due to the fact that circular patterns were difficult to identify in those images. 1516 events were categorized as muons, 17027 events were categorized as non-muons and 4231 events were categorized as ambiguous. The cuts on the muon identification parameters were optimized on the first half of the visually categorized events so that no non-muon events passed. The cuts that resulted in the greatest number of muons were found to be:

\[
\begin{align*}
AP &> 0.011 \times TD + 6.6 \\
TD &< 182 \\
10 \leq N\text{pix} \leq 79
\end{align*}
\]

Figure 5 shows the \(AP/TD\) distribution for each category of event with \(10 \leq N\text{pix} \leq 79\). The upper-left plot shows all events, the upper-right plot shows muon events, the lower-left plot shows non-muon events and the lower-right plot shows ambiguous events. The red lines indicate the cuts on \(AP\) and \(TD\). The results of applying these cuts to the first half of the visually categorized events are shown in Table 1. These cuts were then applied to the other half of the visually categorized events and were found to produce a pure muon sample with an estimated efficiency of approximately 29 percent. The results of applying the cuts to the second half of the visually categorized events are shown in Table 2. These cuts were found to produce highly pure muon samples when applied to other runs, as shown in Table 3.

Table 1: The distribution of the first half of the visually categorized events before and after muon identification cuts.

| Total | Muons | Non-muons | Ambiguous |
|-------|-------|-----------|------------|
| Before | 10921 | 795       | 7918       | 2208       |
| After  | 239   | 225       | 0          | 14         |

Table 2: The distribution of the second half of the visually categorized events before and after muon identification cuts.

| Run   | Events | Passing cuts | False positives |
|-------|--------|--------------|-----------------|
| 47511 | 274991 | 1617         | 5               |
| 40839 | 184048 | 1105         | 2               |
| 40840 | 166224 | 730          | 4               |
| 40841 | 184451 | 1101         | 3               |

Table 3: The number of events scanned, number of events passing cuts and number of false positives (non-muons identified by eye but passing cuts) for four runs.

6 Conclusions

The Hough transform was found to be effective at parametrizing the circular pixel patterns produced by muons in the VERITAS cameras. The cuts on the muon identification parameters obtained from the accumulator array were optimized using the visually categorized events and found to produce highly pure muon samples when applied to other runs. This technique is currently being implemented in the VERITAS offline analysis software. Upon completion, the technique will be used to identify muons for calibration work. Future research will involve improving the technique by investigating the efficiencies of different muon identification parameters as well as assessing the usefulness of the Hough transform algorithm for event reconstruction.
