An appealing mechanism for inducing multiferroicity in materials is the generation of electric polarization by a spatially varying magnetization that is coupled to the lattice through the spin-orbit interaction. Here we describe the reciprocal effect, in which a time-dependent electric polarization induces magnetization even in materials with no existing spin structure. We develop a formalism for this dynamical multiferroic effect in the case for which the polarization derives from optical phonons, and compute the strength of the phonon Zeeman effect, which is the solid-state equivalent of the well-established vibrational Zeeman effect in molecules, using density functional theory. We further show that a recently observed behavior – the resonant excitation of a magnon by optically driven phonons – is described by the formalism. Finally, we discuss examples of scenarios that are not driven by lattice dynamics and interpret the excitation of Dzyaloshinskii-Moriya-type electromagnons and the inverse Faraday effect from the viewpoint of dynamical multiferroicity.

I. INTRODUCTION

Multiferroic materials, with their simultaneous magnetism and ferroelectricity, are of considerable fundamental and technological interest because of their cross-coupled magnetic and electric external fields and internal order parameters. Particularly intriguing are the class of multiferroics in which a non-centrosymmetric ordering of the magnetic moments induces directly a ferroelectric polarization. Prototypical examples are chromium chrysoberyl, Cr$_2$BeO$_4$~[1], in which the effect was first proposed, and terbium manganese, TbMnO$_3$, which provided the first modern example and detailed characterization~[2,3]. The mechanism responsible for the induced ferroelectric polarization in these materials is the Dzyaloshinskii-Moriya interaction~[4,5] as first proposed by Katsura et al.~[6]: Electric polarization, $\mathbf{P} \sim \mathbf{M} \times (\nabla \times \mathbf{M})$, emerges in spatial spin textures as a consequence of the lowest order coupling between polarization and magnetization, $\mathbf{P} \cdot (\mathbf{M} \times (\nabla \times \mathbf{M}))$, in the usual Ginzburg-Landau picture~[7,8].

From a symmetry point of view a reciprocal effect, in which magnetization is induced by ferroelectric polarization, must also exist. The time-reversal and spatial-inversion properties of magnetization and polarization – $\mathbf{M}$ is symmetric under space inversion and anti-symmetric under time reversal, whereas $\mathbf{P}$ is symmetric under time reversal and anti-symmetric under space inversion – indicate that the product $\mathbf{M} \cdot (\mathbf{P} \times \partial_t \mathbf{P})$ couples $\mathbf{M}$ and $\mathbf{P}$ at the same lowest order as $\mathbf{P} \cdot (\mathbf{M} \times (\nabla \times \mathbf{M}))$. It follows that a magnetization

$$\mathbf{M} \sim \mathbf{P} \times \partial_t \mathbf{P} \quad (1)$$

develops in the presence of an appropriate dynamical polarization. This mechanism of induced magnetization by time-dependent polarization provides a dynamical analogy of the usual static multiferroicity. While the generation of polarization by spatial spin textures is now well established both experimentally and in first-principles calculations (see for example Refs. [12,15]), discussions of the reciprocal dynamical effect are scarce, perhaps surprisingly so, since the idea is rooted in the classical induction of a magnetic field by a circulating current. One notable example is the proposal by Dzyaloshinskii and Mills [16] that it is the cause of the observed paramagnetism and specific heat increase in a ferroelectric insulator [17]; this analysis has been largely unrecognized to date.

The purpose of this paper is to develop the formalism of this dynamical multiferroic effect and to describe observable effects that it leads to. We begin by deriving a formalism for magnetic moments induced by phonons that allows computation of their magnitudes using first-principles electronic structure calculations. This allows us to provide a general derivation of the phonon Zeeman effect as the solid-state equivalent to the well-established vibrational Zeeman effect in molecules and to analyze the limits under which the effect will be experimentally observable. Next, we give an explanation for a recently observed behaviour, the resonant magnon excitation of a magnon using optically driven phonons reported by Nova et al [18], in terms of dynamical multiferroicity. Finally we discuss the connection of dynamical multiferroicity to effects that are not related to lattice dynamics, specifically Dzyaloshinskii-Moriya-type electromagnons and the inverse Faraday effect.

Our investigation is particularly timely in light of recent progress in the ability to manipulate materials in the time domain to generate nonequilibrium states of matter with properties that differ from or are inaccessible in the static limit. Examples include the ultrafast structural phase transition in (La,Ca)MnO$_3$ driven by melting of orbital order [19] and the report of enhanced superconducting transition temperature in the high-T$_c$ cuprate yt-
trium barium copper oxide \([20,22]\). In addition, a number of theoretical proposals exist, for example predictions within Floquet theory of emerging topological states \([23]\), and of temporal control of spin-currents \([24]\). Our work in turn contributes to this growing field of “dynamical materials design” by providing an additional mechanism – time-dependence of polarization – through which novel states can be dynamically generated.

**FORMALISM FOR DYNAMICAL MULTIFERROICITY**

We begin by reviewing the duality between the time dependence of \(P\) and spatial gradient of \(M\) that we discussed in the introduction and that is illustrated in Fig. 1. A spatially varying magnetic structure induces a ferroelectric polarization; if the gradient is zero, the polarization vanishes. Both, the sense of the spin spiral and the direction of polarization, persist statically in one of two degenerate ground states: If the sense of the spin spiral is reversed, the polarization inverts. In the case of the dynamical multiferroic effect, a temporally varying polarization induces a magnetization; if the time derivative is zero, the magnetization vanishes. Here, both, the sense of the spin spiral and the direction of the magnetization, persist dynamically in one of two degenerate ground states of the dynamical system: If the sense of the rotating polarization is inverted, the magnetization reverses. A quasi-static state of the magnetization is realized when the rotation of the polarization is steady. The induced magnetization can then couple to lattice and magnetic degrees of freedom of the system, as we will show in various examples. We emphasize that magnetism can be induced by a time-varying polarization in a previously non-magnetic system, just as a spatially varying magnetization can induce a polarization in a system that is previously nonpolar.

For the general case of a magnetization induced by two perpendicular dynamical polarizations that are oscillating sinusoidally with frequencies \(\omega_1\) and \(\omega_2\) and a relative phase shift of \(\varphi\) we write the time-dependent polarization as

\[
P(t) = \begin{pmatrix} P_1(t) \\ P_2(t) \\ 0 \end{pmatrix} = \begin{pmatrix} A_1 \sin(\omega_1 t + \varphi) \\ A_2 \sin(\omega_2 t) \\ 0 \end{pmatrix},
\]

where one of the components can, in principle, also be static (\(\omega_1\) or \(\omega_2\) equal to zero). Evaluating Eq. (1) with this polarization we obtain

\[
M(t) \sim \begin{pmatrix} \frac{\omega_+}{2} \sin(\omega_- t + \varphi) \\ -\frac{\omega_-}{2} \sin(\omega_+ t + \varphi) \end{pmatrix} A_1 A_2 \hat{z}.
\]

A time-varying magnetization is induced that is oriented perpendicular to the spatial orientations of both polarizations. The magnetization consists of a superposition of a large-amplitude oscillation with the difference frequency, \(\omega_- = \omega_1 - \omega_2\), and a small-amplitude oscillation with the sum frequency, \(\omega_+ = \omega_1 + \omega_2\). If the frequencies are equal, \(\omega_1 = \omega_2\), the induced magnetization is static.

**DYNAMICAL MULTIFERROICITY MEDIATED BY PHONONS**

The polar nature of optical phonons means that they can induce time-dependent polarization, and in turn dynamical multiferroicity, in materials. We write the polarization, \(P\), caused by the displacing atoms in a normal-mode vibration as the Born effective charges, \(Z^*\), of the ions multiplied by the normal coordinates, \(Q\), of the phonon modes, \(P = Z^* Q\). (Note that another approach is to use a Berry phase calculation; this was shown to lead to similar results by Ceresoli and Tosatti \([25,26]\).) The connection to the usual relation between magnetic moment and angular momentum \([27]\) is revealed by rewriting Eq. (1) to obtain

\[
M = \gamma Q \times \dot{Q} = \gamma L,
\]

where \(\gamma\) is a gyromagnetic ratio and \(L = Q \times \dot{Q}\) an angular momentum. Optical phonons with perpendicular polarity induce circular motions of the ions (ionic loops) whose individual magnetic moments combine to produce an effective macroscopic magnetic moment, as depicted in Fig. 2. The direction of \(M\) is determined by the sense of the ionic loop. The magnetic moment of phonons is the solid-state equivalent of the vibrational magnetic moment of molecules \([28]\).

For a many-body system, such as a phonon, the simple tensorial relation of Eq. (4) has generally to be extended. The total magnetic moment per unit cell given by the sum of the moments caused by the circular motion of

![Diagram](image)
each ion [29]:

$$M = \sum_i m_i = \sum_i \gamma_i L_i. \tag{5}$$

Here $m_i$ is the magnetic moment of ion $i$, $L_i$ its angular momentum and $\gamma_i$ its gyromagnetic ratio, and the sum is over all ions in one unit cell. The angular momentum results from the motion of the ion along the eigenvectors of all contributing phonon modes [30]:

$$L_i = \sum_{\alpha, \beta} Q_{i\alpha} \dot{Q}_{i\beta} = \sum_{\alpha, \beta} Q_{i\alpha} q_{i\alpha} \times q_{i\beta}, \tag{6}$$

where we wrote the displacement vector of ion $i$ corresponding to mode $\alpha$, $Q_{i\alpha}$, in terms of a product of the normal mode coordinate amplitude, $Q_\alpha$, with the unit eigenvector, $q_{i\alpha}$: $Q_{i\alpha} = Q_\alpha q_{i\alpha}$. Indices $\alpha$ and $\beta$ run over all contributing phonon modes. The gyromagnetic ratio tensor is the effective charge to mass ratio of the ion:

$$\gamma_i = \frac{e_{i} Z_{i}^{*}}{2 M_i}, \tag{7}$$

where $Z_{i}^{*}$ is the Born effective charge tensor of ion $i$ and $M_i$ its mass.

We will now rewrite the magnetic moment of Eq. (5) in terms of the phononic system. We insert the expression for the angular momentum of Eq. (6) in Eq. (5) to obtain:

$$M = \sum_i \gamma_i \sum_{\alpha, \beta} Q_{\alpha} \dot{Q}_{\beta} q_{i\alpha} \times q_{i\beta}
= \sum_{\alpha < \beta} (Q_{\alpha} \dot{Q}_{\beta} - Q_{\beta} \dot{Q}_{\alpha}) \sum_i \gamma_i q_{i\alpha} \times q_{i\beta}. \tag{8}$$

Now we write the difference of the normal mode coordinates as an angular momentum, analogously to Eq. (6):

$$(Q_{\alpha} \dot{Q}_{\beta} - Q_{\beta} \dot{Q}_{\alpha}) = Q_{\alpha \beta} \times Q_{\alpha \beta} = L_{\alpha \beta}, \tag{9}$$

where $Q_{\alpha \beta}$ contains the normal coordinates of the modes $\alpha$ and $\beta$ in the basis of their symmetric representation. The remaining part of $M$ resembles a gyromagnetic ratio, therefore we write Eq. (8) as:

$$M = \sum_{\alpha < \beta} \gamma_{\alpha \beta} L_{\alpha \beta} = \sum_{\alpha < \beta} m_{\alpha \beta}, \tag{10}$$

where

$$\gamma_{\alpha \beta} = \sum_i \gamma_i q_{i\alpha} \times q_{i\beta} \tag{11}$$

is the gyromagnetic ratio vector and $L_{\alpha \beta}$ the angular momentum of a system of phonons. The induced magnetic moments, $m_{\alpha \beta}$, are generated by the ionic loops caused by pairs of phonon modes, $\alpha$ and $\beta$. For only two contributing phonon modes Eq. (10) reduces to the simple tensorial form

$$M = m_{12} = \gamma_{12} L_{12} = \gamma_{12} Q_{12} \times \dot{Q}_{12}. \tag{12}$$

We note that all quantities in this section, particularly the Born effective charge tensors, $Z_{i}^{*}$, and the phonon eigenvectors, $q_{i\alpha}$, can be calculated from first principles using standard density functional theory methods.

**Phonon Zeeman effect**

Next we discuss the Zeeman splitting of degenerate phonon modes, building on the early work extending the well-established vibrational Zeeman effect in molecules [31] to solids by Anastassakis [32] and Rebane [33], as well as a derivation for cubic perovskites by Ceresoli [20] and a phenomenological analysis by Dzylaloshinskii and Mills [16]. Here we derive a general formalism for the phonon Zeeman effect that is amenable to computation using density functional theory via the quantities defined in the previous section.

Consider two degenerate phonon modes ($\omega_1 = \omega_2 = \omega_0$) polarized along perpendicular axes and shifted in phase by $\varphi \neq 0$. Eq. (4) then reduces to

$$M(0) \sim \omega_0 \sin(\varphi) A_1 A_2 \dot{z}. \tag{13}$$

We see that the magnetization induced by the atomic motions is static and its magnitude depends only on the amplitude of the lattice vibrations, on their frequency, and on the phase shift between the two sinusoidal fields, reaching a maximum at $\varphi = \pi / 2$. If an external magnetic field, $B$, is applied to the system, this induced magnetization interacts with it via the usual Zeeman coupling, with the result that the degeneracy of the phonon modes is lifted.

The Lagrangian describing the interaction of this magnetic moment with an externally applied magnetic field is:

$$\mathcal{L}(Q, \dot{Q}) = \frac{1}{2} \dot{Q}^2 - \frac{e_{i} Z_{i}^{*}}{2 M_i} |Q|^2 + B \cdot M, \tag{14}$$

where $B$ is the external magnetic field, $Q = Q_{12} = (Q_1, Q_2, 0)$ contains the normal coordinates of two degenerate phonon modes and $M$ is their magnetic moment.
as in Eq. [12]. We can write the Lagrangian component wise as:

\[
\mathcal{L}(Q_1, Q_2, \dot{Q}_1, \dot{Q}_2) = \frac{1}{2} \dot{Q}_1^2 + \frac{1}{2} \dot{Q}_2^2 - \frac{\omega^2}{2} Q_1^2 - \frac{\omega^2}{2} Q_2^2 + \gamma B_z (Q_2 \dot{Q}_1 - Q_1 \dot{Q}_2),
\]

where \( \gamma = \gamma_{12} \) is the gyromagnetic ratio as derived in Eqs. [11][12], and \( B_z \) is the \( z \) component of the magnetic field. After a Fourier transformation,

\[
\begin{align*}
Q_\alpha & \rightarrow Q_\alpha = Q_{\alpha \omega} e^{i \omega t} \\
Q_\alpha^2 & \rightarrow Q_{\alpha \omega} Q_{\alpha \omega}^* \\
Q_{\alpha \omega} \dot{Q}_{\beta \omega} & \rightarrow \frac{1}{2} \left( Q_{\alpha \omega} \dot{Q}_{\beta \omega}^* + Q_{\alpha \omega}^* \dot{Q}_{\beta \omega} \right),
\end{align*}
\]

the Lagrangian becomes

\[
\mathcal{L}(Q_\omega, Q_\omega^*) = Q_\omega A Q_\omega^* ,
\]

where \( Q_\omega = (Q_{1 \omega}, Q_{2 \omega}, 0) \) contains the normal mode coordinates in Fourier space, and

\[
A = \left( \begin{array}{cc} \omega^2 - \omega_0^2 & 2i \gamma B_2 \omega \\ -2i \gamma B_2 \omega & \omega^2 - \omega_0^2 \end{array} \right).
\]

We solve the determinant for the zone centre (\( \omega \rightarrow \omega_0 \)) and obtain a splitting of the degenerate phonon modes:

\[
\omega = \omega_0 \sqrt{1 \pm \frac{2 \gamma B}{\omega_0}} \approx \omega_0 \pm \gamma B_2 .
\]

The splitting is sketched in Fig. 3 for a magnetic moment aligned parallel and antiparallel to an external field, corresponding to a left- and right-handed sense of the phonons. Notably the phonon Zeeman effect is independent of the magnitude of the phonon magnetic moment and hence the amplitude of the lattice vibrations. It is therefore present in optical modes excited, for example thermally or due to zero-point fluctuations [16][31], and does not require intense optical pumping.

We estimate the magnitude of the effect for the tetragonal phase of strontium titanate, SrTiO\(_3\), using density functional theory. (Please see the “Computational methods for phonon calculations” section for details of the calculation.) Our calculated low frequency degenerate \( E_g \) phonon modes lie at 1 THz, and their gyromagnetic ratio as calculated with Eq. [11] is \( \gamma = 0.9 \times 10^7 \text{T}^{-1} \text{s}^{-1} \).

A recently observed example of the dynamical multiferroic effect is the resonant excitation of magnons through the frequency-dependent magnetic moment of a system of phonons. Consider two nondegenerate phonon modes \( (\omega_1 \neq \omega_2) \) with perpendicular polarity. Setting \( \varphi = 0 \) without loss of generality, Eq. [3] then reduces to

\[
M(t) \sim \left[ \frac{\omega_-}{2} \sin(\omega_- t) - \frac{\omega_+}{2} \sin(\omega_+ t) \right] A_1 A_2 \dot{\hat{z}} .
\]

We obtain an induced magnetization that varies in time as a superposition of a large-amplitude oscillation with the difference frequency, \( \omega_- \), and a small-amplitude oscillation with the sum frequency, \( \omega_+ \).

Such a situation was recently realized experimentally by Nova et al. by applying an intense linearly polarized terahertz pulse along the [110] direction in the \( a-b \) plane of orthorhombic perovskite-structure erbiun ferrite, ErFeO\(_3\) [13]. The pulse drives the high-frequency \( IR \)-active phonon modes \( B_{3a} \) and \( B_{2a} \), with polarization along the \( a \) and \( b \) lattice vectors. Due to the \( Pbnn \) symmetry of ErFeO\(_3\), these modes have slightly different eigenfrequencies (17.0 and 16.2 THz). Intriguingly, the spontaneous excitation of a magnon at 0.75 THz, close to the difference frequency, was observed. Our analysis above indicates that this behavior is a manifestation of the dynamical multiferroic effect: The large-amplitude ion ensures low frequency phonons, while the light B/A-site ion and the oxygens make up a large percentage of the motion in the normal mode. A further approach to increasing the magnitude of the effect is to identify materials with dynamically varying Born effective charges which will lead to an additional contribution to the angular momentum proportional to \( (\partial \mathbf{Z}^*) \mathbf{Q} \).
part of the induced magnetic moment, $\mathbf{M}$, oscillates with the difference frequency $\omega_{\alpha} = 0.8\,\text{THz}$, sufficiently close to the 0.75 THz magnon of ErFeO$_3$ [36], which is thus resonantly excited by $\mathbf{M}$.

Indeed a dynamical simulation of the evolution of the phonons with parameters computed from density functional theory confirms the behaviour predicted phenomenologically in Eq. (22). (See the “Computational methods for phonon calculations” section for details of the calculation.) In Fig. 4a we show the induced magnetic moment as calculated by Eq. (10) and in Fig. 4b the normal mode coordinate of the high-frequency IR-active B$_{3u}$ and B$_{2u}$ modes following an excitation with an ultrashort terahertz pulse. The small-amplitude oscillation of $\mathbf{M}$ with the sum frequency is negligible and only the large-amplitude oscillation with the difference frequency contributes. The induced magnetic moment peaks at the order of magnitude of the nuclear magneton with $|\mathbf{M}| \approx 0.1\mu_N$ per unit cell. It decays together with the IR modes over the timescale of a few picoseconds; experimentally the induced magnon was found to survive for at least 35 ps [18].

While the phonon Zeeman effect is independent of the magnitude of the phonon magnetic moment, the resonant effect discussed here is quadratic in the amplitude of the dynamical polarization and therefore dependent on the intensity of the exciting terahertz pulse. At high pulse intensities an anharmonic coupling of the excited IR phonons to Raman-active phonons was shown to be relevant in ErFeO$_3$ [37]. These modes do not contribute to the gyromagnetic ratio however, and we can therefore neglect the effect of nonlinear phononics in the above analysis.

### Computational methods for phonon calculations

We calculated the phonon eigenfrequencies and eigenvectors, and the Born effective charges of SrTiO$_3$ and ErFeO$_3$ from first-principles using the density functional theory formalism as implemented in the Vienna ab-initio simulation package (VASP) [38, 39] and the frozen-phonon method as implemented in the phonopy package [40]. We used the default VASP PAW pseudopotentials with Er 4f electrons treated as core states. We converged the Hellmann-Feynman forces to $10^{-5}\,\text{eV/Å}$ using a plane-wave energy cut-off of 700 eV and a $7\times7\times5$ k-point mesh to sample the Brillouin zone for SrTiO$_3$ and 850 eV, $6\times6\times4$ for ErFeO$_3$. For the exchange-correlation functional we chose the PBEsol [41] form of the generalized gradient approximation (GGA) and imposed a Hubbard correction of $U = 3.7\,\text{eV}$ and a Hund’s exchange of $J = 0.7\,\text{eV}$ on the Fe $3d$ states in ErFeO$_3$. Our fully relaxed structures with lattice constants $a = 5.51\,\text{Å}$ and $c = 7.77\,\text{Å}$ for SrTiO$_3$ and $a = 5.19\,\text{Å}$, $b = 5.56\,\text{Å}$, and $c = 7.52\,\text{Å}$ for ErFeO$_3$ fit reasonably well to the experimental values of Refs. [42, 43], as do our calculated phonon eigenfrequencies [18, 36, 44–46]. Our calculated values for the highest IR phonon frequencies are 16.52 THz for the B$_{3u}$ and 15.95 THz for the B$_{2u}$ mode in ErFeO$_3$. For the time evolution of IR phonons after a pulsed optical excitation, we obtain the time-dependent normal mode coordinates, $Q$, by numerically solving the dynamical equations of motion:

$$\ddot{Q}_\alpha + \kappa_\alpha \dot{Q}_\alpha + \omega_\alpha^2 Q_\alpha = F,$$

where $\kappa_\alpha$ is the friction coefficient and $\omega_\alpha$ the eigenfrequency of mode $\alpha$. The periodic driving force $F$ models the terahertz pulse in a realistic fashion with gaussian shape with an amplitude of $10\,\text{MV/cm}$, and a finite
BEYOND LATTICE DYNAMICS

In the previous two examples we showed how the magnetic moment arising from a system of phonons couples lattice and magnetic degrees of freedom. In the following we discuss examples in which the time-dependent polarization is not caused by lattice dynamics.

Dzyaloshinskii-Moriya-type electromagnons

The existence of electromagnons – that is spin waves excited by a.c. electric fields – was demonstrated ten years ago in multiferroic materials with an incommensurate (cycloidal or helicoidal) magnetic structure [17]. In the original report, the interaction was shown to be mediated through conventional Heisenberg coupling of spins, leading to a phonon-magnon hybridization that makes the magnon electroactive (and is therefore called an electromagnon) [17,54]. A second mechanism for generating electromagnons, in which electroactive excitation of the spin spiral occurs via the Dzyaloshinskii-Moriya interaction, has also been identified [54–59]. We show in the following that the description of these electromagnons from the viewpoint of dynamical multiferroicity is equivalent to the previously introduced formalism via the inverse effect of the Dzyaloshinskii-Moriya interaction [55].

The standard description of a Dzyaloshinskii-Moriya-type electromagnon in a helical magnet is through the coupling of the spin degrees of freedom of the cycloid, \( S_n \), with a uniform lattice displacement, \( u \). The ferroelectric polarization is given by \( P_{FE} \propto e_{ij} \times (S_i \times S_j) \), where \( e_{ij} \) is the vector connecting the sites \( i \) and \( j \). The component \( n \) of the lattice displacement that couples to the rotation of the spin plane is parallel to its rotation axis, \( u^n \parallel (S_i \times S_j) \). An a.c. electric field, \( E \parallel u^n \), then induces a magnetization, \( m \parallel e_{ij} \), and excites an electromagnon when it matches the frequency of the eigenmode of the spin cycloid [55]. Specifically in TbMnO\(_3\) with a magnetic field applied along \( b \), the spin cycloid lies in the \( a-b \) plane. Since \( (S_i \times S_j) \parallel c \) and \( e_{ij} \parallel b \), the resulting \( P_{FE} \parallel a \). The a.c. electric field component of sub-terahertz radiation, \( E \parallel c \), then induces a magnetization, \( m \parallel b \), and excites a Dzyaloshinskii-Moriya-type electromagnon when it matches the eigenfrequency of the spin cycloid at 0.63 THz [57]. To disentangle this clutter of alignments, we illustrate the symmetry in Fig. 5. Note that a cooperative contribution of the ferroelectric polarization from symmetric magnetostriction has been reported [60,61], which, however, leaves our symmetry analysis here unaffected.

This situation is exactly consistent with the formalism of dynamical multiferroicity when the two perpendicular polarizations in Eq. (2) are given by \( \mathbf{P} = (P_1(0), 0, P_2(t)) \), where \( P_1(0) \equiv P_{FE} \left( \omega_1 = 0, \varphi = \pi/2 \right) \) and \( P_2(t) \equiv E(t) \left( \omega_2 = \omega_0 \right) \). Eq. (1) then reduces to

$$\mathbf{M}(t) \sim \omega_0 \cos(\omega_0 t) A_1 A_2 \hat{y}. \quad (24)$$

The formalism predicts an induced magnetization that oscillates with the frequency of the terahertz radiation, \( \omega_0 \), identical to the magnetization described above within the inverse Dzyaloshinskii-Moriya formalism, \( \mathbf{M}(t) \equiv \mathbf{m} \).

Inverse Faraday effect

Finally, we show that the inverse Faraday effect, which describes the generation of a static magnetization in a material when irradiated with circularly polarized light, can also be interpreted from the viewpoint of dynamical multiferroicity. The inverse Faraday effect was first demonstrated in the 1960’s [62–64] and experienced a massive revival in the last decade, after it was shown that it can be used to control magnetization non-thermally with photomagnetic pulses [65]. The standard description of the effect is

$$\mathbf{M}(\omega) = \chi(\omega) \mathbf{E}(\omega) \times \mathbf{E}^*(\omega), \quad (25)$$

where \( \mathbf{M} \) is the induced magnetization, \( \chi \) the magneto-optical susceptibility and \( \mathbf{E} \) the electric field component of the circularly polarized light. The electric field induces perpendicular time-varying polarizations in the material and the connection to dynamical multiferroicity is revealed by rewriting Eq. (25) in the time domain:

$$\mathbf{M}(t) = \chi(t) \mathbf{E}(t) \times \partial_t \mathbf{E}(t) \sim \mathbf{P} \times \partial_t \mathbf{P}. \quad (26)$$

The perpendicular time-dependent polarizations induced by the circularly polarized light both oscillate with the frequency of the light (\( \omega_1 = \omega_2 = \omega_0 \)) and are shifted in width in both time (fwhm=130 fs) and frequency (peak frequency 19.5 THz, fwhm=6.5 THz) [18].
phase by \( \phi = \pi/2 \). Eq. (3) therefore reproduces the induced static magnetization of the inverse Faraday effect:

\[
M(0) \sim \omega_0 A_1 A_2 \hat{z}. \quad (27)
\]

Note that the investigation of the inverse Faraday effect has been extended in recent years by microscopic theories that also describe ultrafast timescales, as well as the case of linearly polarized light; these extensions are beyond the scope of the analogy provided here.

### DISCUSSION

In summary, we have introduced the concept of dynamical multiferroicity and shown that it provides a straightforward unifying interpretation of four diverse phenomena, summarized in Table I: i) the Zeeman splitting of phonon spectra in a magnetic field, ii) resonant magnon scattering, iii) electromagnon coupling, and iv) the inverse Faraday effect. In the case of i) and ii), in which the multiferroicity is mediated by lattice dynamics, we showed that the dynamical multiferroic coupling can be calculated quantitatively using standard density functional theory methods, and we performed such calculations for representative materials in each case. Since the term nonlinear is used in both optics (for example second-harmonic generation) and phononics (for example cubic and higher-order phonon-phonon interactions), we also clarify the order (linear or higher order and in which parameter) of the excitations for the four cases. First, in the cases of SrTiO\(_3\), ErFeO\(_3\), and DyFeO\(_3\), the materials are centrosymmetric, so a nonlinear second-harmonic optical response to the terahertz pulse is not possible. In the case of TbMnO\(_3\), second-harmonic generation occurs at higher energies than the sub-THz radiation used in the example (see for example Ref. [70]). In addition, while cubic and higher-order non-linear phononic coupling has indeed been demonstrated in some of these materials (see for example, Ref. [71]), a detailed analysis in the case of ErFeO\(_3\), the phenomena described here are not driven by non-linear phononic effects. The phonon Zeeman effect in SrTiO\(_3\) is independent of the amplitude of the degenerate phonons and requires no external excitation and so is zeroth-order in the polarization amplitude. The magnon excitation in ErFeO\(_3\) depends on the quadratic term in the phonon amplitude and so is nonlinear in the amplitude of the driven time-dependent polarization, \( P(t) \). As for the Dzyaloshinskii-Moriya-type electromagnon excitation, the induced magnetization is linear in \( P(t) \) (with the perpendicular ferroelectric polarization being static), while the inverse Faraday effect is nonlinear in \( P(t) \) due to the excitation with circularly polarized light.

The phonon Zeeman splitting that we analyze here is distinct from previously discussed interactions between phonons and magnetism in magnetic materials. These include the phonon angular momentum arising from spin-phonon interaction, the splitting of acoustic phonons due to the spin-orbit interaction, the splitting of non-degenerate Raman-active phonon modes accompanying a ferroelectric to paraelectric phase transition and the magnetic-field dependence of the phonon frequencies in Ce compounds. In contrast, the phonon Zeeman effect does not require magnetic ions. The report of a splitting of degenerate phonons due to the interaction with magnetoexcitons in graphene is a fascinating phenomenon, but also a different mechanism from the phonon Zeeman effect. It is further distinct from the phonon Hall effect proposed for acoustic phonons as an analogue of the anomalous Hall effect.

With the increased availability of intense THz sources of radiation, we anticipate that additional manifestations of dynamical multiferroicity will be revealed over the next years.
years. Reciprocally, we expect that the effect will be used to engineer new behaviors that are not accessible in the static domain. In this context, we point out that dynamical multiferroicity provides a unit-cell analogue of an electric motor, in which the time-dependent polarization acts as a nanoscale electromagnetic coil to generate magnetic fields. This analogy might open a pathway to unforeseen technological applications.

ACKNOWLEDGMENTS

We thank G. Aeppli, A. Cavalleri, M. Fiebig, T. F. Nova, and A. Scaramuccia for useful discussions. This work was supported by the ETH Zürich, by Dr. Max Rössler and the Walter Haefner Foundation through the ETH Zürich Foundation, by US DoE E3B7 and by the ERC Advanced Grant program numbers 291151 and DM-321031. Calculations were performed at the Swiss National Supercomputing Centre (CSCS) supported by the project IDs s624 and p504.
