The magnetic field effect on the phase diagram of the organic Mott system $\kappa-(BEDT-TTF)_2\text{Cu[N(CN)$_2$]Br}$ in which the bandwidth was tuned by the substitution of deuterated molecules was studied by means of the resistivity measurements performed in magnetic fields. The lower critical point of the first-order Mott transition, which ended on the upper critical field $H_{c2}$-temperature plane of the superconductivity, was determined experimentally in addition to the previously observed upper critical end point. The lower critical end point moved to a lower temperature with the suppression of $T_c$ in magnetic fields and the Mott transition recognized so far as the S-shaped curve reached $T = 0$ when $H > H_{c2}$ in the end.

Metal-insulator (MI) transitions have been one of the central issues in strongly correlated electron systems. Among the various types of MI transitions, the Mott transition is the most attractive phenomenon, which arises from an electron-electron interaction in a wide range of materials. Mott insulator derives from a large electrical Coulomb repulsion energy $U$ with respect to the bandwidth $W$. Metal transitions can occur in two ways in a Mott insulator: one can change the strength of the interaction $U/W$, while maintaining the required band-filling value and is referred to as a bandwidth-controlled Mott transition or one can introduce carriers with the required density, while maintaining $U/W$ and is referred to as a band-filling-controlled Mott transition. The former case occurs, for example, in vanadium oxides and molecular conductors, while the latter occurs in high-$T_c$ cuprate superconductors.

Organic charge transfer salts based on the donor molecule bis(ethylenedithio)tetrathiafulvalene, abbreviated as BEDT-TTF or ET, have been recognized as molecular conductors, while the latter occurs in high-$T_c$ cuprate superconductors.

FIG. 1: Temperature dependence of the in-plane resistivity in magnetic fields perpendicular to the a-c plane of κ-[{(h8-ET)$_{1-x}$-(d8-ET)$_x$}]$_2$Cu[N(CN)$_2$]Br for (a) $x = 0.4$, (b) $x = 0.5$, (c) $x = 0.6$, and (d) $x = 0.8$. White arrows indicate $T_{MI}$. The inset of Fig. 1(d) shows $T_{MI} \simeq 31$ K (black arrow) at which the upper Mott MI transition occurs in addition to the lower $T_{MI}$ transition due to the reentrance of the S-shaped curve.

substitution ratio $x$ denotes the nominal mole ratio to the fully deuterated ET molecule in the crystallization. No apparent impurity effect in the electronic state other than the bandwidth modulation was observed for such a soft chemical substitution although a small increase in the scattering time within the clean-limit superconductivity was observed in the quantum magnetic oscillation experiments.

The in-plane resistivity in magnetic fields was measured by the dc four-terminal method, with the current parallel to the a-c plane. The angle $\theta$ denotes the magnetic field direction relative to the b-axis, which is perpendicular to the a-c plane. The rotation axis was parallel to the current direction as shown in the inset of Fig. 2(b). All the samples measured were cooled slowly at almost the same rate with $-0.1$ K/min from 290 K to 80 K, $-0.01$ K/min from 80 K to 70 K and keeping the temperature at 75 K for 900 min, and $-0.1$ K/min from 70 K to 1.5 K. After the initial cooling, the temperature of the sample did not exceed 45 K during the resistivity measurements.

Figure 1 shows the temperature dependence of the in-plane resistivity $\rho$ in magnetic fields perpendicular to the a-c plane of κ-[{(h8-ET)$_{1-x}$-(d8-ET)$_x$}]$_2$Cu[N(CN)$_2$]Br for (a) $x = 0.4$, (b) $x = 0.5$, (c) $x = 0.6$ and (d) $x = 0.8$. For the $x = 0.4$ sample of Fig. 1(a), the $\rho(T)$ curve from room temperature to the superconducting transition temperature $T_c \simeq 11$ K represents the characteristic features observed in previous studies for the $x = 0$ sample at $H = 0$ T. In addition, the usual normal state behavior appears at low temperatures; a constant residual resistivity of the metal is observed for $H > H_{c2}$. In magnetic fields below $H_{c2}$, the superconducting transition curves show typical fan-shaped broadening, reflecting a vortex liquid state with large fluctuations. It may be difficult to evaluate the exact value of $T_c$ and $H_{c2}$ from the gradual transition curve of the resistivity in magnetic fields. This is basically because the change between the vortex liquid and normal states is not defined as a thermodynamic phase transition but observed as a crossover. In this measurement, $T_c(H)$ is defined as a temperature of initial decrease from the normal resistivity value. Although the $T_c$ value determined by this means may have ambiguity in part, those are in good agreement with the mean field $T_c$ obtained by the scaling analysis of fluctuations for the magnetization.

For the samples with $x \geq 0.5$, resistivity anomalies at $T_{MI}$ (marked with white arrows) are observed on the curves in the normal state at magnetic fields $H > H_{c2}$ below $T_c( H = 0 \ T)$ in Figs. 1(b) ($x = 0.5$) and 1(c) ($x = 0.6$). In addition, a marked temperature hysteresis of the resistivity appears below $T_{MI}$. With an increase in $x$, $T_{MI}$ shifts to a higher temperature and the magnitude of the jump in the resistivity increases. In the case of the $x = 0.8$ sample, $T_{MI}$ already appears at $H = 0$ T above $T_c$. Such anomalies associated with the jumps in and the hysteresis of the resistivity indicate that the first-order MI Mott transition occurs at $T_{MI}$ in the normal states for $H > H_{c2}$ ($x = 0.5$ and 0.6) or $H = 0$ ($x = 0.8$). The observed MI transitions are considered to be the same as those observed in the Mott insulator κ-(BEDT-TTF)$_2$Cu[N(CN)$_2$]Cl under hydrostatic helium gas pressure.

In addition, another anomaly in the resistivity (marked with a black arrow in the inset of Fig. 1(d)) appears in the $x = 0.8$ sample at around 30 K. The Mott transition curve of this system has been known to exhibit the characteristic S-shaped curvature. Hence, the observed anomaly at higher temperatures can be considered to result from the high $T$ paramagnetic insulator-metal (Fermi liquid)-low $T$ antiferromagnetic Mott insulator reentrant transition.

A gradual decrease in the resistivity is found in the samples with $x$ ranging from 0.5–0.8 below $T_{MI}$ for $H < H_{c2}$, although the system should be in the Mott insulating state. This decrease may be due to the metal-insulator phase separation caused by the first-order Mott transition. The metallic domains resulting from the phase separation become superconducting below $H_{c2}$ and reduce the total resistivity of the dominant Mott insulator. Therefore, on the resistivity curves for samples with $x$ ranging 0.5–0.8 under magnetic fields, the jumps in and the temperature hysteresis of the resistivity should be attributed to the Mott insulating domains, which are dominant in the bulk sample; moreover, the decrease in the resistivity and its recovery by applying magnetic fields may be caused by the metallic/superconducting minor fragments.

The most important experimental finding of this study
is that the jump in the resistivity disappears in a superconducting state with a finite resistivity due to the vortex flow, i.e., the vortex liquid state, below \( T_{c2} \), as shown in Figs. 1(b) and 1(c). Figure 2 shows the magnetic-field dependence of \( T_{MI} \) and the dependence of \( T_{MI} \) on the magnetic field direction at low temperatures in the \( x = 0.6 \) and 0.8 samples. The open and closed circles in Figs. 2(a) and 2(b) denote \( T_{MI} \) determined from down and up sweeps of the temperature, respectively. The shaded area indicates the temperature hysteresis of \( T_{c2} \). The dashed curve in Fig. 2(a) represents \( H_{c2}(T) \) or \( T_{c}(H) \) for the \( x = 0 \) sample. In the \( x = 0.8 \) sample, \( T_{MI} \), which is always higher than \( T_{c} \) does not change with the magnetic field and its direction. In contrast, resistive anomalies such as the jump expected at \( T_{MI} \) for the \( x = 0.6 \) sample are not observed on the smooth resistivity curve in the vortex liquid state below \( H_{c2} \) for \( H = 2 \) and 1 T, as shown in Fig. 2(c). This clearly demonstrates that the MI transition does not occur in the vortex liquid state, i.e., \( T_{MI} \) starts to appear just above \( H_{c2}(T = T_{MI}) \). It is noted that these phenomena require the condition \( T_{MI} \leq T_{c} \) and the bulk superconductivity to be below \( H_{c2} \). A similar field-induced transition has been observed in pressurized \( \kappa-(h\beta-ET)_{2}Cu[N(CN)_{2}]Cl \). In order to confirm the relationship between \( T_{MI} \) and \( T_{c} \) in \( H \), the dependence of \( T_{MI} \) on the magnetic field direction was determined. The large anisotropy of \( H_{c2} \) for magnetic fields between the direction perpendicular and parallel to the \( a-c \) plane enables us to control the \( H_{c2} \) value in a tilted magnetic field. The dashed curve in Fig. 2(b) shows \( T_{c} \) in magnetic fields based on the anisotropic effective mass model. The resistivity curves in Fig. 2(d) indicate that \( T_{MI} \) appears only above \( T_{c} \) in the tilted constant magnetic field of 15 T. This is the same case of a varying magnetic field as shown in Fig. 2(c). It can be concluded from both experiments on the dependence of \( T_{MI} \) on the magnetic field and its direction that the MI Mott transition does not occur in the superconducting state with a finite resistivity below \( H_{c2} \), i.e., the vortex liquid state.

Figure 3 shows the summary of \( T_{MI} \) and \( T_{c} \) in the \( T-H-x \) phase diagram of \( \kappa-(h\beta-ET)_{1-x}(d\beta-ET)_{x}Cu[N(CN)_{2}]Br \). The substitution ratio \( x \) corresponds to the hydrostatic pressure \( P \) (MPa) = 35 – 15x for \( \kappa-(h\beta-ET)_{2}Cu[N(CN)_{2}]Cl \) and \( \kappa-(d\beta-ET)_{2}Cu[N(CN)_{2}]Br \) by using partly deuterated ET molecules by Taniguchi et al. It must be emphasized that in the present phase diagram, the first order Mott transition curve is terminated also at the lower crit-
At 7 K under 30 MPa. Kagawa of helium, for example, the liquid-solid transition occurs above approximately 10 K for avoiding the solidification. Previous studies have been performed for the MI transition and superconductivity for magnetic fields. For details, see the text.

Below \( T_{\text{cr}}^L \) in the superconducting phase, the trace of the S-shaped curve of \( T_{\text{MI}}(x) \) is not observed, although it is difficult to isothermally investigate the transition property between the superconducting and the antiferromagnetic Mott insulating phases by means of the chemical substitution, as performed in the present study. Helium gas pressure experiments can approach this issue by varying the pressure isothermally. However, most of the previous studies have been performed for the MI transition above approximately 10 K for avoiding the solidification of helium, for example, the liquid-solid transition occurs at 7 K under 30 MPa. Kagawa et al. have measured the isothermal pressure dependence of the resistivity at the MI transition in magnetic fields. At the MI transition above \( T_c(H) \), the resistivity shows a clear sharp jump that represents the first-order transition. In addition, other previous results also have given some indications of the first-order transition at which a steep increase in the resistivity occurs in magnetic fields. On the other hand, below \( T_c(H) \) in the vortex liquid state, the behavior of the MI transition in the resistivity have become somewhat broad, which implies that the nature of the first-order transition becomes weak in spite of being at a lower temperature. The results reported so far may also be suggestive of the existence of \( T_{\text{cr}}^L \).

Figure 4 schematically shows the effect of the magnetic field on the relationship between the Mott transition and superconductivity for magnetic fields \( H < H_{c2} \). On the basis of Fig. 4, we phenomenologically explain the behavior of the resistivity reported so far in a similar series of organic superconductors in the close vicinity of the Mott transition in magnetic fields. The lower critical end point \( T_{\text{cr}}^L(H, x) \) of the first-order Mott transition curve moves to lower temperatures and toward a smaller \( x \) (higher pressure) along with the suppression of \( T_c \) by magnetic fields. In \( H > H_{c2} \) in the end, the first-order transition curve may approach \( T = 0 \). During this process of a decrease in \( T_{\text{cr}}^L \) with an increase in the magnetic field, field-induced MI transitions occur in the hatched region shown in Fig. 4. In a part of the hatched region for \( T_c(H) = T_{\text{cr}}^L < T < T_c(0) \), the successive superconducting-normal metal-insulator transitions occur due to the magnetic fields while only the MI transition appears above \( T_c(0) \). Based on the present measurements, we would emphasize that there is no evidence for a direct transition from the superconducting to the insulating state by magnetic fields as it was claimed in Ref. [17].

The existence of \( T_{\text{cr}}^L \) in the \( T_c(H) \) plane may imply that the superconducting coherence developed below \( T_c(H) \) suppresses the Mott insulating phase at lower temperatures. Further theoretical investigations are necessary to understand the correlation between superconductivity and the Mott insulating states under magnetic fields. Finally, we would like to comment on the reentrant AFI transition below \( T_c \), as claimed in the early helium gas pressure experiments on \( \kappa-(h8-\text{ET})_2\text{Cu[N(CN)]}_2\text{Cl} \). The early experiments indicated the significant proximity of the AFI phase to the superconducting phase even for \( H = 0 \). However, the reentrant transition always appeared around 7 K, even the different pressures in the range of 30–55 MPa. This difference may be caused by a drop or inhomogeneity in the actual pressure applied to the sample due to the solidification of liquid nitrogen at this temperature (7 K)-pressure (30 MPa) range.

In summary, details of the phase diagram for the organic Mott system \( \kappa-(d8-\text{ET})_2\text{Cu[N(CN)]}_2\text{Br} \) in magnetic fields is presented. The lower critical end point of the first-order Mott transition, which is terminated in the \( H_{c2}(T) \) plane, is found experimentally in addition to the upper critical end point. A theoretical study on the stability of the Mott insulator and the adjacent superconductivity by considering the development of each order parameter and phase coherence in magnetic fields is necessary to understand this issue.

A part of this work was performed at HFLSM, IMR, Tohoku University. This work was partly supported by a Grant-in-Aid for Scientific Research (Nos. 16076201, 17340099, and 18654056) from MEXT and JSPS, Japan.
