Inapproximability of
NP-Complete Variants of Nash Equilibrium

Per Austrin    Mark Braverman    Eden Chlamtáč

Abstract

In recent work of Hazan and Krauthgamer (SICOMP 2011), it was shown that finding an ε-
approximate Nash equilibrium with near-optimal value in a two-player game is as hard as finding
a hidden clique of size $O(\log n)$ in the random graph $G(n, 1/2)$. This raises the question of whether
a similar intractability holds for approximate Nash equilibrium without such constraints. We
give evidence that the constraint of near-optimal value makes the problem distinctly harder: a
simple algorithm finds an optimal $1/2$-approximate equilibrium, while finding strictly better than
$1/2$-approximate equilibria is as hard as the Hidden Clique problem. This is in contrast to the
unconstrained problem where more sophisticated algorithms, achieving better approximations,
are known.

Unlike general Nash equilibrium, which is in PPAD, optimal (maximum value) Nash equilib-
rium is NP-hard. We proceed to show that optimal Nash equilibrium is just one of several known
NP-hard problems related to Nash equilibrium, all of which have approximate variants which
are as hard as finding a planted clique. In particular, we show this for approximate variants of
the following problems: finding a Nash equilibrium with value greater than $\eta$ (for any $\eta > 0$,
even when the best Nash equilibrium has value $1 - \eta$), finding a second Nash equilibrium, and
finding a Nash equilibrium with small support.

Finally, we consider the complexity of approximate pure Bayes Nash equilibria in two-player
games. Here we show that for general Bayesian games the problem is NP-hard. For the special
case where the distribution over types is uniform, we give a quasi-polynomial time algorithm
matched by a hardness result based on the Hidden Clique problem.

1 Introduction

The classical notion of Nash equilibrium is the most fundamental concept in the theory of non-
cooperative games. In recent years, there has been much work on the complexity of finding a Nash
equilibrium in a given game. In particular, a series of hardness results culminated in the work of Chen et. al [CDT09], who showed that even for two-player (bimatrix) games, the problem of computing a Nash equilibrium is PPAD-complete, and thus unlikely to be solvable in polynomial
time.

Therefore, it makes sense to consider the complexity of approximate equilibria. In particular, a
notion which has emerged as the focus of several works is that of an $\varepsilon$-approximate Nash equilibrium,
or $\varepsilon$-equilibrium for short, where neither player can gain more than $\varepsilon$ (additively) by defecting to
a different strategy (without loss of generality, all payoffs are scaled to lie in the interval $[0, 1]$).
A straightforward sampling argument of Lipton et al. [LMM03] shows that in every game, there
exist $\varepsilon$-equilibria with support $O(\log n/\varepsilon^2)$, and so they can be found in quasi-polynomial time
$n^{O(\log n/\varepsilon^2)}$ by exhaustive search.
On the other hand, finding good polynomial time approximations has proved more challenging. While finding a $\frac{1}{2}$-equilibrium turns out to be quite simple \cite{DMP09}, more complicated algorithms have given a series of improvements \cite{DMP07, BBM10, TS08}, where the current best known is the 0.3393-equilibrium shown by Tsaknakis and Spirakis \cite{TS08}. A major open question in this area is whether or not there exists a PTAS for Nash Equilibrium (note that the algorithm of Lipton et al. gives a quasi-polynomial time approximation scheme for the problem).

Recently, Hazan and Krauthgamer \cite{HK11} have attempted to provide evidence for the optimality of the QPTAS of Lipton et al. \cite{LMM03}, by showing a reduction from a well-studied and seemingly intractable problem (which can also be solved in quasi-polynomial time) to the related problem of finding an $\varepsilon$-equilibrium with near maximum value (the value of an equilibrium is the average of the payoffs of the two players).

The problem they reduce from is the Hidden Clique Problem: Given a graph sampled from $G(n, \frac{1}{2})$ with a planted (but hidden) clique of size $k$, find the planted clique. Since with high probability the maximum clique in $G(n, \frac{1}{2})$ is of size $\left(2 - o(1)\right)\log n$, it is easy to see that for constant $\delta > 0$, one can distinguish between $G(n, \frac{1}{2})$ and $G(n, \frac{1}{2})$ with a planted clique of size $k > \left(2 + \delta\right)\log n$ in quasi-polynomial time by exhaustive search over all subsets of $\left(2 + \delta\right)\log n$ vertices. It is also not hard to extend this to an algorithm which finds the hidden clique in quasi-polynomial time.

On the other hand, the best known polynomial time algorithm, due to Alon et al. \cite{AKS98} only finds cliques of size $\Omega(\sqrt{n})$. In fact, Feige and Krauthgamer \cite{FK03} show that even extending this approach by using the Lovász-Schrijver SDP hierarchy, one still requires $\Omega(\log n)$ levels of the hierarchy (corresponding to $n^{\Omega(\log n)}$ running time to solve the SDP) just to find a hidden clique of size $n^{1/2-\varepsilon}$. The only possible approach we are aware of for breaking the $\Omega(\sqrt{n})$ barrier would still (assuming certain conjectures) only discover cliques of size $\Omega(n^c)$ for some constant $c > 0$ \cite{FK08, BV09}.

Hazan and Krauthgamer show that finding a near-optimal $\varepsilon$-equilibrium is as hard as finding hidden cliques of size $C\log n$, for some universal constant $C$. Here, by near-optimal we mean having value close to maximum possible value obtained in an actual Nash equilibrium. Subsequently, Minder and Vilenchik \cite{MV09} then improved this hardness to planted cliques of size $(2 + \delta)\log n$ for arbitrarily small $\delta > 0$. Here, we will rely on the hardness assumption for hidden cliques of size $C\log n$ for any constant $C$, and will not concern ourselves with optimizing the value of $C$.

### 1.1 A Sharp Result For Near-Optimal Approximate Nash

It is important to note that the problem considered in \cite{HK11} is not equivalent to finding an unconstrained $\varepsilon$-equilibrium. In light of the results of \cite{HK11, MV09} it is natural to ask to what extent the hardness for near-optimal approximate equilibrium gives an indication of hardness for unconstrained approximate equilibrium. Indeed, \cite{HK11}, in their concluding remarks, ask whether their methods can be used to rule out a PTAS for unconstrained Nash equilibrium. One of the messages of this paper is that these two problems are quite different in terms of approximability and that one should not yet be overly pessimistic about the possibility for a PTAS for unconstrained Nash equilibrium. Indeed, while there is a a polynomial time algorithm to find a 0.3393-equilibrium, we show that finding a near-optimal $\left(\frac{1}{2} - \eta\right)$-equilibrium is hard.

**Theorem 1.1** (Informal). For every $\eta > 0$, finding a near-optimal $\left(\frac{1}{2} - \eta\right)$-approximate equilibrium is as hard as finding a hidden clique of size $C\log n$ in $G(n, \frac{1}{2})$.

\footnote{There is a small caveat: the reduction of \cite{MV09} only certifies the presence of a hidden clique (i.e. distinguishes the graph from the random graph $G(n, \frac{1}{2})$ w.h.p.) but does not identify the vertices of the clique.}
As mentioned above, there is a simple polynomial time algorithm to find a $\frac{1}{2}$-equilibrium, and we show that this algorithm can be extended to find a $\frac{1}{2}$-equilibrium with value at least that of the best exact equilibrium:

**Theorem 1.2** (Informal). There exists a polynomial time algorithm to find a $\frac{1}{2}$-approximate equilibrium with value at least that of the optimal true equilibrium.

Thus, Theorem 1.1 is tight and unlike unconstrained Nash equilibrium, where stronger techniques yield approximations better than $\frac{1}{2}$, near-optimal Nash equilibrium does not admit efficient "non-trivial" approximations (assuming the Hidden Clique problem is hard).

1.2 The Bigger Picture: Hardness for NP-hard Variants of Nash

Just like with unconstrained $\varepsilon$-equilibrium, finding a near-optimal $\varepsilon$-equilibrium can be done in quasi-polynomial time using the algorithm of [LMM03]. However, the exact version – finding a maximum value Nash equilibrium – is known to be NP-hard [GZ89] and therefore harder than its unconstrained counterpart which is in PPAD [Pap94]. In fact, maximum value Nash is one of several optimization variants of Nash equilibrium which are NP-complete. Other variants include: determining whether a bimatrix game has more than one Nash equilibrium [GZ89], finding a Nash Equilibrium with minimum support [GZ89], and determining whether there exists an equilibrium with value at least $1 - \frac{1}{n}$ or all equilibria have value at most $\varepsilon/n$ (even for arbitrarily small $\varepsilon = \varepsilon(n) > 0$) [CS03]. We show that approximate-equilibrium variants of these problems are also as hard as Hidden Clique.

For the problem of obtaining any non-trivial approximation to the optimal value of a Nash equilibrium, we prove the following theorem.

**Theorem 1.3** (Informal). For every $\eta > 0$, finding an $\varepsilon$-equilibrium with value at least $\eta$ is as hard as finding a hidden clique of size $C \log n$ in $G(n, \frac{1}{2})$, even in a game having an equilibrium of value $1 - \eta$.

For the case of determining whether a game has more than one equilibrium, note that by continuity considerations, every two-player game has an infinite number of $\varepsilon$-equilibria. Thus, the appropriate approximate analog is to consider the problem of finding two $\varepsilon$-equilibria with (at least) a certain total variation distance between them. We show that this problem is also as hard as Hidden Clique.

**Theorem 1.4** (Informal). For all sufficiently small $\varepsilon > 0$, determining whether a game has two different $\varepsilon$-approximate equilibria (say, having statistical distance at least $3\varepsilon$) is as hard as finding a hidden clique of size $C \log n$ in $G(n, \frac{1}{2})$.

We then move to the problem of finding an equilibrium with small support. Recall that by [LMM03], there exist $\varepsilon$-Nash equilibria with support $O(\log n/\varepsilon^2)$. It is also known that for any $\eta > 0$, in certain two-player games all $(\frac{1}{2} - \eta)$-equilibria must have support at least $\log n/(1 + \log(1/\eta))$ [FNS07] (the threshold of $\frac{1}{2}$ is tight, since the simple $\frac{1}{2}$-equilibrium of [DMP09] has support 3). As an approximate-equilibrium variant of the Minimum Support Equilibrium problem, we consider the problem of finding an $\varepsilon$-equilibrium with support at most some threshold $t$, and prove the following hardness result.

**Theorem 1.5** (Informal). For every $\eta > 0$, finding a $(\frac{1}{2} - \eta)$-equilibrium with support size $C \log n$ is as hard as finding a hidden clique of size $C' \log n$ in $G(n, \frac{1}{2})$. 

3
This can be seen as a complexity-theoretic analogue of the lower bound of [FNS07] mentioned above. Again, this contrasts with the situation for unconstrained Nash equilibrium, which is guaranteed to exist, and admits stronger approximations.

While these are all negative results, we again would like to stress that there is a positive message to this story: these problems are hard because they are approximate versions of NP-complete problems, not because they are approximate variants of Nash equilibrium. Therefore, these results should not be viewed as indications that Nash equilibrium does not have a PTAS.

### 1.3 The Complexity of Approximate Pure Bayes Nash Equilibria

Finally, we consider the problem of approximating pure Bayes Nash Equilibria (BNE) in two-player games. Bayesian games model the situation where the players’ knowledge of the world is incomplete. In a Bayesian game, both players may be in one of a number of different states, known as types, representing what each player knows about the state of the world, and the payoff of each player depends on the type of both players in addition to their strategies. The types are distributed according to some joint distribution and are not necessarily independent. A pure strategy for a Bayesian game assigns to each type a strategy that the player plays when she is in that type. In a pure BNE, conditioning on any given type for a given player, the player cannot gain by changing his strategy for that type. See Section 6 for precise definitions.

Conitzer and Sandholm [CS03] have shown that determining whether a given two-player game has a pure BNE is NP-complete. We show that this holds also for approximate pure BNE.

**Theorem 1.6 (Informal).** Let \( \varepsilon = 0.004 \). Then given a Bayesian game that admits a pure BNE, it is NP-hard to find a pure \( \varepsilon \)-BNE for the game.

However, this hardness result relies heavily on the joint distribution of the players’ types being non-uniform (in fact, not even product distribution). We show that when the distribution over type pairs is uniform, there is in fact a quasi-polynomial time algorithm for \( \varepsilon \)-approximate pure BNE (when a pure BNE exists).

**Theorem 1.7 (Informal).** For every \( \varepsilon > 0 \) there is a quasipolynomial time algorithm to find a pure \( \varepsilon \)-BNE in two-player Bayesian games with uniformly distributed types and in which a pure BNE exists.

We remark that this algorithm extends easily to arbitrary product distributions over types but in order to keep the notation simple we restrict our attention to the uniform case.

The algorithm is tight: it follows immediately from our hardness for Small Support Equilibrium that this problem is also hard as Hidden Clique.

**Theorem 1.8 (Informal).** For every \( \eta > 0 \), finding a \((\frac{1}{4} - \eta)\)-approximate pure BNE in a two-player Bayesian games with uniformly distributed types and in which a pure BNE exists is as hard as finding a hidden clique of size \( C \log n \).

### 1.4 Organization

In Section 3 we prove the results relating to approximate equilibria with good value: Theorem 1.1 (Section 3.2), Theorem 1.2 (Section 3.4), and Theorem 1.3 (Section 3.3).

In Section 4 we prove Theorem 1.4 by a black-box application of Theorem 1.3. In Section 5 we prove Theorem 1.5 using similar techniques as for the hardness results of Section 3. In Section 6 we prove our results for Bayesian games, Theorems 1.6, 1.7, and 1.8.
2 Preliminaries

A bimatrix game \( G = (M_{\text{row}}, M_{\text{col}}) \) is a game defined by two finite matrices, \( M_{\text{row}} \) and \( M_{\text{col}} \), and two players: the row player and the column player. We assume throughout that the game is normalized so that both matrices have values in the interval \([0, 1]\). The row and column players choose strategies \( x \) and \( y \) respectively, where \( x, y \) are nonnegative vectors satisfying \( \sum_i x_i = \sum_j y_j = 1 \). A pure strategy is one with support 1 (i.e. a vector with 1 in one entry and 0 in the rest). The row (resp. column) player’s payoff is given by \( x^\top M_{\text{row}} y \) (resp. \( x^\top M_{\text{col}} y \)).

A Nash equilibrium is a pair of strategies \( (x, y) \) such that neither player has any incentive to deviate to a different strategy, assuming the other player does not deviate. Formally, in an equilibrium, for all \( i, j \) we have \( e_i^\top M_{\text{row}} y \leq x^\top M_{\text{row}} y \) and \( x^\top M_{\text{col}} e_j \leq x^\top M_{\text{col}} y \). An \( \varepsilon \)-approximate Nash equilibrium, or \( \varepsilon \)-equilibrium for short, is a pair of strategies \( x, y \) where each player has incentive at most \( \varepsilon \) to deviate. That is, for all \( i, j \),

\[
e_i^\top M_{\text{row}} y \leq x^\top M_{\text{row}} y + \varepsilon \quad \text{and} \quad x^\top M_{\text{col}} e_j \leq x^\top M_{\text{col}} y + \varepsilon.
\]

The value of a pair of strategies, denoted \( v_G(x, y) \), is the average payoff of the two players, i.e.,

\[
v_G(x, y) = \frac{1}{2} (x^\top M_{\text{row}} y + x^\top M_{\text{col}} y) = \sum_{i,j} x_i y_j \frac{M_{\text{row}}(i, j) + M_{\text{col}}(i, j)}{2}.
\]

For a vector \( x \in \mathbb{R}^n \) and \( S \subseteq [n] \), we write \( x_S \) for the projection of \( x \) to the coordinates \( S \). We write \( \|x\| = \sum_{i=1}^n |x_i| \) for the \( \ell_1 \) norm of \( x \). Thus, for a strategy (in other words, a probability distribution) \( x \in [0, 1]^n \) we write \( \|x_S\| \) for the probability that the player plays an element of \( S \).

Further, for a set \( S \subseteq [n] \) of strategies, we use \( v_{G|S}(x, y) \) to denote the value of \( (x, y) \) conditioned on both players playing in \( S \). Formally,

\[
v_{G|S}(x, y) = \mathbb{E}_{i \sim x, j \sim y} \left[ \frac{M_{\text{row}}(i, j) + M_{\text{col}}(i, j)}{2} \right] = \frac{v_G(x_S, y_S)}{\|x_S\| \cdot \|y_S\|}.
\]

(If \( \|x_S\| = 0 \) or \( \|y_S\| = 0 \), \( v_{G|S}(x, y) \) is undefined.)

Given an undirected graph \( G = (V, E) \), and (not necessarily disjoint) vertex sets \( S_1, S_2 \subseteq V \), we will denote by \( E(S_1, S_2) \) the set of ordered pairs \( \{(i, j) \in S_1 \times S_2 \mid (i, j) \in E \text{ or } i = j \} \). We will refer to \( d(S_1, S_2) = |E(S_1, S_2)| / (|S_1||S_2|) \) as the density of the pair \( S_1, S_2 \).

Finally, we shall make repeated use of the following standard Chernoff bound.

**Lemma 2.1** (Chernoff bound). Let \( X_1, \ldots, X_m \) be i.i.d. \( \{0, 1\} \) random variables and let \( \mu = \frac{1}{m} \mathbb{E}[\sum X_i] \). Then

\[
\Pr \left[ \frac{1}{m} \sum X_i \geq \mu + \varepsilon \right] \leq e^{-2\varepsilon^2 m}.
\]

3 Approximate Equilibria With Good Value

3.1 The Reduction

In this section we describe the general reduction that we use to prove Theorems 1.1 and 1.3 and describe its properties. This reduction also forms the basis for the reductions we use to prove Theorems 1.4, 1.5, and 1.8. It is based on the reduction of [HK11].

As in [HK11], our soundness analysis proceeds by using the approximate equilibrium to find a dense bipartite subgraph of \( G \). The following lemma shows that this is sufficient to recover the hidden clique.
Lemma 3.1 ([HK11] Lemma 5.3)). There exist universal constants $c_1$ and $c_2$ such that the following holds. Let $G$ be a sample from $G(n, \frac{1}{2})$ with a hidden clique of size $C \log n$ for some $C \geq c_1$. Then, given a pair of vertex sets $S_1, S_2 \subseteq [n]$ of size $c_2 \log n$ and density $d(S_1, S_2) \geq 5/9$ we can in polynomial time reconstruct the hidden clique (with high probability over $G$).

The lemma is slightly different from Lemma 5.3 of [HK11]: there we start with a bipartite subgraph of density $3/5$ instead of $5/9$ but this minor difference only changes the value of the constant $c_2$ – the lemma holds for any constant density strictly larger than $\frac{5}{9}$.

Let us now describe the reduction. It is controlled by three parameters $\alpha, \beta, \gamma \in (0, 1)$. Setting these parameters appropriately gives the various hardness results.

Reduction 3.2. Let $G = (V, E)$ be an $n$ vertex graph and $A$ its adjacency matrix (with 1s on the diagonal). Then, for parameters $\alpha, \beta, \gamma \in (0, 1)$, we define a (random) bimatrix game $G := G(G, \alpha, \beta, \gamma)$ as follows. Let $N = n^c$ where $c = (c_2+1) \log 1/\beta$ for the universal constant $c_2$ of Lemma 3.1. Pick a random $N \times n$ matrix $B$ whose entries are i.i.d. $\{0, 1\}$ variables with expectation $\beta$. Then $G = (M_{\text{row}}, M_{\text{col}})$, where the payoff matrices are:

$$
M_{\text{row}} = \begin{pmatrix}
\alpha A & 0 \\
B & \gamma J
\end{pmatrix},
M_{\text{col}} = \begin{pmatrix}
\alpha A & B^\top \\
0 & \gamma J
\end{pmatrix},
$$

where $J$ is the all-ones $N \times N$ matrix.

We conclude this section with an additional lemma which shows how to obtain a dense bipartite subgraph given an approximate equilibrium of $G$ with certain properties. This lemma (and its proof) is analogous to [HK11] Lemma 5.2, but as we need it in larger generality we also give the proof.

Lemma 3.3. Let $G$ be as in Reduction 3.2. Fix any $s \in [0, 1]$, $t \in [0, 1]$ and $\varepsilon \in (0, 1]$ such that $1 - t - 3\sqrt{s}/2 \geq \alpha + \varepsilon$, and let $(x, y)$ be an $\varepsilon$-approximate equilibrium of $G$ with the following two properties:

- Both $\|x[a]\| \geq 1 - t$ and $\|y[a]\| \geq 1 - t$.
- The conditional value $v_{G[a]}(x, y) \geq (1 - s)\alpha$.

Then, given $(x, y)$ as above, we can efficiently find vertex sets $S_1, S_2 \subseteq [n]$ each of size $c_2 \log n$ and density $d(S_1, S_2) \geq 5/9$.

In the proof of Lemma 3.3 we shall use the following simple claim, which is analogous to [HK11] Claim 5.3:

Claim 3.4. Let $S \subset [n]$ be a set of size $|S| \leq c_2 \log n$. Then, w.h.p. over $G$, in any $\varepsilon$-equilibrium in the above game, the probability mass a column (or row) player may place on such a set $S$ is at most $\varepsilon + \alpha$.

The proof of the claim follows by noting that for such $S$, with high probability, there is a row $i$ of $B$ such that $B_{ij} = 1$ for all $j \in S$. Indeed, the probability that such a row does not exist is exactly

$$
\left(1 - \beta^{-|S|}\right)^N \leq \exp(-n^{-c_2 \log 1/\beta}N) = \exp(-n^{\log 1/\beta}).
$$

We omit the remaining details as they are identical to [HK11] Claim 5.3.
Proof of Lemma 3.3. Let $\tilde{x}, \tilde{y} \in [0,1]^n$ be the strategies $x$ and $y$ conditioned on playing in $[n]$. That is, $\tilde{x} = x_{[n]}/\|x_{[n]}\|$, and $\tilde{y} = y_{[n]}/\|y_{[n]}\|$. The second given property of the strategy pair $(x, y)$ can be rephrased as $\tilde{x}^T \tilde{y} \geq 1 - s$.

Let

$$S'_1 = \left\{ i \in [n] : e_i^T \tilde{y} \geq 1 - 2\sqrt{s}/3 \right\}.$$

To obtain a lower bound on the cardinality $|S'_1|$, we shall bound $\|x_{S'_1}\|$ by $\varepsilon + \alpha$ and then appeal to the claim. By the first given property of $(x, y)$, we have

$$\|x_{S'_1}\| \geq 1 - t - \|x_{[n]\setminus S'_1}\| \geq 1 - t - \|\tilde{x}_{[n]\setminus S'_1}\|,$$

which is similar to the argument for $|S'_1|$.

Thus we have $\|x_{S'_1}\| \geq 1 - t - 3\sqrt{s}/2 \geq \varepsilon + \alpha$, and so by the claim, $|S'_1| \geq c_2 \log n$. Truncate $S'_1$ by taking any arbitrary subset $S_1 \subseteq S'_1$ of cardinality $|S_1| = c_2 \log n$.

Now let $\pi \in [0,1]^n$ be the uniform distribution over $S_1$. Note that $\pi^T \tilde{y} \geq 1 - 2\sqrt{s}/3$. Let

$$S'_2 = \left\{ j \in [n] : \pi^T A e_j \geq 5/9 \right\}.$$

The argument to lower bound $|S'_2|$ is similar to the argument for $|S'_1|$. We get

$$\|\tilde{y}_{[n]\setminus S'_2}\| = \Pr_{j \sim \tilde{y}} \left[ 1 - \pi^T A e_j > 4/9 \right] \leq \frac{2\sqrt{s}/3}{4/9} = 3\sqrt{s}/2.$$ 

and therefore

$$\|x_{S'_2}\| \geq 1 - t - 3\sqrt{s}/2 \geq \varepsilon + \alpha,$$

as desired. Again, we can truncate $S'_2$ by taking a subset $S_2 \subseteq S'_2$ of cardinality $|S'_2| = c_2 \log n$. By construction $d(S_1, S_2) \geq 5/9$, and we are done.

3.2 Hardness for $\varepsilon$ close to $\frac{1}{2}$

To obtain Theorem 1, the main requirement is to set $\alpha = \frac{1}{2} + O(\eta)$. The values of $\beta$ and $\gamma$ are essentially irrelevant in this case – the only thing needed is that $\beta$ is bounded away from both 0 and $\alpha$ and that $\gamma \leq \frac{1}{2}$.

Lemma 3.5. Let $\alpha = \frac{1}{2} + t$, $\gamma \leq \frac{1}{2}$ and $G$ be the game of Reduction 3.2. Then for any pair of strategies $(x, y)$ with value at least $\nu_G(x, y) \geq \alpha - t^2$ it holds that $\|x_{[n]}\|$ and $\|y_{[n]}\|$ are both at least $1 - t$.

Proof. Let $p = \|x_{[n]}\|$ and $q = \|y_{[n]}\|$. As the value of any outcome outside the $\alpha A$ block is at most $\frac{1}{2}$, we have that the value of $(x, y)$ is at most

$$pq + \alpha t - \frac{1}{2} = \alpha t + \frac{1}{2},$$

so that if the value is at least $\alpha - t^2$ we have

$$tpq + \frac{1}{2} \geq \alpha - t^2$$

$$pq \geq \alpha - \frac{1}{2} \frac{1}{t} = 1 - t.$$

Since $p, q \in [0,1]$, it follows that they are both at least $1 - t$. 

\end{proof}
Observation 3.6. Let \((x, y)\) be any pair of strategies with value \(v_G(x, y) \geq \frac{1}{2}\) and \(\|x\| > 0\), \(\|y\| > 0\). Then \(v_G(x, y) \geq v_G(x, y)\), provided that \(\gamma \leq \frac{1}{2}\).

Plugging this into Lemma 3.3, we can now easily complete the proof of hardness for \(\varepsilon\) close to \(\frac{1}{2}\).

**Theorem 3.7** (Detailed Statement of Theorem 1.1). For every \(\eta > 0\) there exist \(\delta = \Omega(\eta^2)\), \(\alpha = \frac{1}{2}\) and universal constant \(C\) not depending on \(\eta\) such that the following holds. Given a graph \(G = (V, E)\) we can in randomized polynomial time construct a bimatrix game \(G\) with maximum value \(\alpha\) (over all strategy pairs) such that, if \(G = G(n, \frac{1}{2})\) with a hidden clique of size \(C\log n\), the following holds (w.h.p. over \(G\) and \(G\)):

**Completeness** There is a Nash equilibrium \((x, y)\) with value \(\alpha\).

**Soundness** Given any \((\frac{1}{2} - \eta)\)-equilibrium with value \(\geq \alpha - \delta\), we can efficiently recover the hidden clique.

**Proof.** Given a graph \(G = (V, E)\), we apply Reduction 3.2 with parameters as follows. For some \(t > 0\) to be determined momentarily, let \(\alpha = \frac{1}{2} + t\), \(\beta = \gamma = 1/3\), \(\delta = t^2\).

For the completeness, we shall show that having both players play uniformly over the hidden clique is an equilibrium. For this to hold, we have to make sure that there is no row in \(B\) with average value at least \(\alpha\) in the positions corresponding to the clique. By Lemma 2.1 and a union bound over all rows of \(B\) we can bound the probability of this happening by

\[
Ne^{-2(\alpha-\beta)^2C\log n} \leq N \cdot n^{-C/18}.
\]

If \(C\) is a sufficiently large universal constant (e.g., \(C = 18 \cdot (c_2 + 1) \log 1/\beta + 1\)) this probability is \(o(1)\) and the completeness property follows.

For the soundness, consider any \((\frac{1}{2} - \eta)\)-approximate equilibrium \((x, y)\) with value at least \(v_G(x, y) \geq \alpha - \delta = \alpha - t^2\). By Lemma 3.3 both \(\|x\|\) and \(\|y\|\) are at least \(1 - t\). Furthermore, by Observation 3.6, we have \(v_G(x, y) \geq \alpha - \delta = \alpha(1 - t^2)\).

Now if \(\frac{1}{2} - \eta \leq 1 - t - 3t/2 - \alpha = \frac{1}{2} - 7t/4\) we can apply Lemma 3.3 and extract a dense bipartite subgraph of \(G\) which can be plugged in to Lemma 3.1 to obtain the hidden clique. Setting \(t = 4\eta/7\) we get the result.

**3.3 Distinguishing Between Low and High Value**

For Theorem 1.3 the choices of all three parameters \(\alpha, \beta, \gamma\) of Reduction 3.2 are important. We are going to set \(\gamma\) close to 0, and \(\alpha > \beta\) both close to 1.

On a high level, the proof has the same structure as that of Theorem 1.1. However, in the current setting Lemma 3.5 and Observation 3.6 do not apply. To arrive at similar conclusions we use a different argument, exploiting the fact that \((x, y)\) is a \(\varepsilon\)-equilibrium. Essentially, the argument is as follows: the off-diagonal blocks \((B\) and \(B^\top)\) are not stable, since there is too much incentive for at least one player to deviate. Therefore, most of the probability mass in an equilibrium is concentrated either in the \(\alpha A\) block, or in the \(\gamma J\) block. However, in the \(\gamma J\) block, the value is too small. So, if the equilibrium has even slightly larger value, its mass must be concentrated in the \(\alpha A\) block. There it has to actually have very large value, since otherwise, there is incentive for both players to deviate to \(B\) and \(B^\top\) to get reward \(\beta\). The rest of the proof follows as before.

Formally, we have the following lemma, showing that (under certain conditions) any \(\varepsilon\)-equilibrium with non-negligible value must satisfy the conditions of Lemma 3.3.
Lemma 3.8. Fix a parameter \( \varepsilon \in (0, 1) \), let \( \alpha - \beta \leq \varepsilon \), and \( \gamma = 4\sqrt{\varepsilon} \) and consider the game \( G \) as in Reduction 2.2.

Then, w.h.p. over \( G \), any \( \varepsilon \)-equilibrium \((x, y)\) with value more than \( 5\sqrt{\varepsilon} \) satisfies:

- Both \( \|x_{[n]}\| \) and \( \|y_{[n]}\| \) are at least \( 1 - \sqrt{\varepsilon} \).

- \( v_{G_{[n]}}(x, y) \geq \alpha - 3\varepsilon \).

Proof. Consider any \( \varepsilon \)-equilibrium \((x, y)\) with value more than \( 5\sqrt{\varepsilon} \). Note that this trivially implies that \( \varepsilon \leq 1/25 \).

Let \( p = \|x_{[n]}\| \) and \( q = \|y_{[n]}\| \) be the probability mass that the row (resp. column) player assigns to the first \( n \) strategies in this equilibrium. We begin with the first item, i.e., the lower bound on \( p \) and \( q \).

Consider the row player’s incentive to deviate by shifting the probability mass in the first \( n \) rows to the uniform distribution over the remaining rows. When the column player is playing outside the first \( n \) columns, this deviation changes the row player’s payoff from 0 to \( \gamma \), and when the column player is playing in one of the first \( n \) columns the row player’s payoff decreases by at most \( \alpha - \beta + o(1) \). Let us ignore this \( o(1) \) term. Since this is an \( \varepsilon \)-equilibrium, we have

\[
p(1 - q)\gamma - pq(\alpha - \beta) \leq \varepsilon, \tag{2}
\]

and so

\[
p(1 - q) \leq \frac{1}{\gamma}(\varepsilon + pq(\alpha - \beta)) \\
\leq \frac{1}{\gamma}(\varepsilon + \alpha - \beta) \\
\leq \sqrt{\varepsilon}/2
\]

Considering also the symmetric argument for the column player, this gives

\[
\max\{p(1 - p), q(1 - q)\} \leq \max\{p(1 - q), q(1 - p)\} \leq \sqrt{\varepsilon}/2, \tag{3}
\]

where the first inequality holds trivially for all \( p, q \in [0, 1] \). The inequality \( p(1 - p) \leq \sqrt{\varepsilon}/2 \) together with the constraint \( \varepsilon \leq 1/25 \) implies that either \( p \leq \sqrt{\varepsilon} \) or \( p \geq 1 - \sqrt{\varepsilon} \). The inequality for \( q \) gives an analogous bound. Moreover, it cannot be the case that \( p < \frac{1}{2} < q \) or \( q < \frac{1}{2} < p \), since then we would have \( \max\{p(1 - q), q(1 - p)\} \geq \frac{1}{4} \), contradicting \( \text{(3)} \). Thus, it follows that either \( p, q \leq \sqrt{\varepsilon} \) or \( p, q \geq 1 - \sqrt{\varepsilon} \).

Let us now exclude the first option. Suppose for contradiction that \( p, q \leq \sqrt{\varepsilon} \). Then the value of the equilibrium is at most

\[
pq\alpha + (p(1 - q) + q(1 - p)) \cdot \frac{1}{2} + (1 - p)(1 - q)\gamma \leq \varepsilon\alpha + \sqrt{\varepsilon}/2 + \gamma \leq \varepsilon\alpha + 4.5\sqrt{\varepsilon} < 5\sqrt{\varepsilon},
\]

contradicting the assumption that \((x, y)\) has value more than \( 5\sqrt{\varepsilon} \). Hence both \( p \) and \( q \) are at least \( 1 - \sqrt{\varepsilon} \).

It remains to give a lower bound on the conditional value \( w := v_{G_{[n]}}(x, y) \) obtained when playing inside \( \alpha A \). As above, consider the incentive for the row player to deviate to the uniform distribution over. To be more precise, we can use \( w \) instead of \( \alpha \) in the bound \( \text{(2)} \). Solving for \( w \) gives

\[
w \geq \beta + \frac{p(1 - q)\gamma - \varepsilon}{pq} \geq \beta - \frac{\varepsilon}{pq} \geq \beta - 2\varepsilon \geq \alpha - 3\varepsilon,
\]

where we used that \( \frac{1}{pq} \leq \frac{1}{(1 - \sqrt{\varepsilon})^2} \leq \frac{25}{16} \leq 2 \) for \( \varepsilon \leq 1/25 \). \( \square \)
Equipped with Lemma 3.8, it is easy to finish the proof of Theorem 1.3.

**Theorem 3.9** (Detailed statement of Theorem 1.3). For every constant $\eta > 0$ there exist $\varepsilon = \Omega(\eta^{2})$ and $C = O(1/\eta^{3})$ such that the following holds. Given a graph $G$, we can in randomized polynomial time construct a bimatrix game $G$ such that, if $G = G(n, \frac{1}{2})$ with a hidden clique of size $C \log n$, the following holds (w.h.p. over $G$ and $G$):

**Completeness** There is a Nash equilibrium $(x, y)$ with both players earning payoff $1 - \eta$.

**Soundness** Given any $\varepsilon$-equilibrium with value $\geq \eta$, we can efficiently recover the hidden clique.

*Proof.* Given a graph $G = (V, E)$, we apply Reduction 3.2 with parameters as follows.

Let $\varepsilon = (\eta/5)^2$, $\alpha = 1 - \eta = 1 - 5\sqrt{\varepsilon}$, $\beta = \alpha - \varepsilon$, and $\gamma = 4\sqrt{\varepsilon}$. Assume without loss of generality that $\eta$ is small enough so that $\alpha > 3/4$.

For the completeness, we proceed as in the proof of Theorem 3.7. We can upper bound the probability that the uniform distribution over the hidden clique is not an equilibrium by

$$Ne^{-2(\alpha - \beta)^2 C \log n} \leq Nn^{-\Omega(C\varepsilon^2)}.$$  

We have $N = n^{O(\log 1/\beta)} = n^{O(n)} = n^{O(\sqrt{\varepsilon})}$. Letting $C$ be a sufficiently large multiple of $1/\varepsilon^{1.5}$ the completeness property follows.

For the soundness analysis, take any $\varepsilon$-approximate equilibrium $(x, y)$ with value at least $5\sqrt{\varepsilon}$. By Lemma 3.8 w.h.p. $(x, y)$ satisfies the conditions of Lemma 3.3 with $t = \sqrt{\varepsilon}$ and $s = \frac{3\varepsilon}{\alpha} \leq 4\varepsilon$.

The only remaining thing to check is the condition $\alpha + \varepsilon \leq 1 - t - 3\sqrt{s}/2$, which is easily verified ($1 - 4\sqrt{\varepsilon}$ is an upper bound for the LHS and a lower bound for the RHS).  

\[\square\]

### 3.4 An Algorithm For Good $\frac{1}{2}$-Approximate Equilibria

In this section we prove Theorem 1.2 by describing a simple algorithm to find a $\frac{1}{2}$-approximate Nash equilibrium with at least as good value as the best exact Nash equilibrium. This shows that the bound on $\varepsilon$ in Theorem 1.1 is tight.

For general $\frac{1}{2}$-approximate equilibria (without any constraint on the value), the following simple algorithm was suggested by Daskalakis, Mehta and Papadimitriou [DMP09]. Start by choosing an arbitrary pure strategy $e_i$ for the row player, let $e_j$ be the column player’s best response to $e_i$, and let $e_k$ be the row player’s best response to $e_j$. Then the following is a $\frac{1}{2}$-equilibrium: let the column player play $e_j$, and let the row player play $e_i$ with probability $\frac{1}{2}$ and $e_k$ with probability $\frac{1}{2}$ (neither player can gain more than $\frac{1}{2}$ by deviating, since each player is playing a best response strategy with probability $\frac{1}{2}$). Thus, every bimatrix game has a $\frac{1}{2}$-approximate equilibrium in which one of the players plays a pure strategy. We show that this is also the case for optimal value $\frac{1}{2}$-equilibria.

**Lemma 3.10.** For every bimatrix game which has a Nash equilibrium of value $v$, there exists a $\frac{1}{2}$-approximate equilibrium with value at least $v$ in which one of the players plays a pure strategy.

*Proof.* Let $M_{row}$ and $M_{col}$ be the payoff matrices for the row and column players, respectively. Let $(x^*, y^*)$ be a Nash equilibrium in this game of value $v := v_G(x^*, y^*)$, and let $v_r$ and $v_c$ be the payoff in this equilibrium to the row and column players, respectively (hence $v = \frac{1}{2}(v_r + v_c)$). Without loss of generality, assume $v_r \geq v_c$ (otherwise, a symmetric argument applies).

Let the pure strategy $e_j$ be some strategy in the support of $y^*$ for which the row player’s payoff is at least $v_r$ (when the row player is playing $x^*$ and the column player $e_j$). Such a strategy exists
since $v_r$ is the expected payoff for the row player when the column player plays according to $y^*$. Furthermore, any such $e_j$ is a best response to $x^*$ since $(x^*, y^*)$ is an equilibrium.

Clearly, if the pair of strategies $(x^*, e_j)$ is a $\frac{1}{2}$-equilibrium we are done, since both the row and column player are getting at least the same payoff as for the pair $(x^*, y^*)$.

If $(x^*, e_j)$ is not a $\frac{1}{2}$-equilibrium, this must be because the row player has incentive $\geq \frac{1}{2}$ to deviate (as the column player is by definition playing a best response). Note that this implies that $v_c \leq v_r \leq \frac{1}{2}$ since the row player’s incentive to deviate can never be more than $1 - v_r$. Let $e_k$ be some best response for the row player, and consider the pair of strategies $(\frac{1}{2}(x^* + e_k), e_j)$. As above, this is a $\frac{1}{2}$-equilibrium, since both players are playing a best response with probability $\frac{1}{2}$.

Furthermore, the payoff for the row player is at least $v_r/2 + (v_r + 1/2)/2 \geq v_r + 1/4 \geq v_r + v_c/2$, and the payoff for the column player is at least $v_c/2$. Thus the value is at least $\frac{1}{2}(v_r + v_c/2 + v_c/2) = v$, and we are done.

Now our algorithm follows immediately.

Proof of Theorem 4.2 Let $M_{\text{row}}$ and $M_{\text{col}}$ be the payoff matrices for the row and column matrices, respectively. By Lemma 3.10 there exists such an equilibrium in which one player plays a pure strategy. Suppose this is the column player (otherwise, a symmetric algorithm applies). Try all possible pure strategies $e_j$ for the column player. For each such strategy, solve the following linear program (if it is feasible):

\[
\begin{align*}
\text{maximize} & \quad \frac{1}{2}x^\top (M_c + M_{\text{row}})e_j \\
\text{subject to} & \quad x^\top M_{\text{col}}e_{j'} \leq x^\top M_{\text{col}}e_j + \frac{1}{2} & \forall j' \\
& \quad (e_i)^\top M_{\text{row}}e_j \leq x^\top M_{\text{row}}e_j + \frac{1}{2} & \forall i \\
& \quad x_i \geq 0 & \forall i \\
& \quad \sum_i x_i = 1
\end{align*}
\]

For at least one strategy $e_j$, this LP is feasible and computes a $\frac{1}{2}$-equilibrium with at least the desired value.

4 Finding A Second Equilibrium

In the following Theorem, $d_{TV}$ refers to the total variation distance between two vectors, i.e., $d_{TV}(x, y) = \frac{1}{2} \sum |x_i - y_i|$.

Theorem 4.1 (Detailed Statement of Theorem 1.4). There is a $C > 0$ such that the following holds for all sufficiently small $\varepsilon > 0$. Given a graph $G$ we can in randomized polynomial time construct a bimatrix game $G'$ which admits a pure Nash equilibrium $(e_i, e_j)$ such that, if $G = G(n, \frac{1}{2})$ with a hidden clique of size $C \log n$, the following holds (w.h.p. over $G$ and $G'$):

Completeness There is a Nash equilibrium $(x, y)$ such that $d_{TV}(e_i, x) = d_{TV}(e_j, y) = 1$.

Soundness Given any $\varepsilon$-approximate equilibrium $(x, y)$ of $G'$ with $d_{TV}(e_i, x) \geq \varepsilon + O(\varepsilon^2)$ or $d_{TV}(e_j, y) \geq \varepsilon + O(\varepsilon^2)$, we can efficiently recover the hidden clique.

Remark 4.2. Note that the bound $\varepsilon + O(\varepsilon^2)$ on the statistical distance is almost tight: given any true equilibrium $(x, y)$ there are $\varepsilon$-approximate equilibria $(x', y')$ with $d_{TV}(x, x') \geq \varepsilon$ and $d_{TV}(y, y') \geq \varepsilon$. 

11
Proof. Given $G$, first construct the game $G$ of Theorem 3.9 with parameter $\eta = 1/10$, so that given a $(4\varepsilon)$-approximate equilibrium of $G$ with value at least $1/10$ we can reconstruct the hidden clique. Let $(M_{\text{row}}, M_{\text{col}})$ be the payoff matrices of $G$ and let $N$ denote their dimension. Consider the new $(N + 1)$-strategy game $G' = (M'_{\text{row}}, M'_{\text{col}})$, with the following payoff matrices.

$$
M'_{\text{row}} = \begin{pmatrix} M_{\text{row}} & 0 \\ \lambda & 1 \end{pmatrix}, \quad M'_{\text{col}} = \begin{pmatrix} M_{\text{col}} & \lambda^T \\ 0 & 1 \end{pmatrix},
$$

(4)

where $\lambda$ is the $1 \times N$ vector with each coordinate equal to $\lambda$. We set $\lambda = 8/10$. $G'$ is a bimatrix game of size $(N + 1) \times (N + 1)$.

Clearly, $(e_{N+1}, e_{N+1})$ is a pure Nash equilibrium of $G'$. Note that for any mixed strategy $x$, we can write $d_{\text{TV}}(e_{N+1}, x) = 1 - x_{N+1}$ so it suffices to obtain good bounds on $x_{N+1}$ and $y_{N+1}$.

Furthermore the completeness case also follows immediately since in that case $G$ has a Nash equilibrium with both players earning payoff $9/10$. As $\lambda \leq 8/10$ this is an equilibrium in $G'$ as well and since it does not use the $(N + 1)$'st strategy we obtain the completeness property.

For the soundness, consider any $\varepsilon$-approximate equilibrium $(x, y)$ of $G'$, let $p = \|x_{[N]}\|$, $q = \|y_{[N]}\|$ be the probability that the row (resp. column) player plays in the original game $G$ where $x_{N+1} < 1 - \varepsilon - O(\varepsilon^2)$ and $y_{N+1} < 1 - \varepsilon - O(\varepsilon^2)$. We need to show that $(x, y)$ can be used to recover the planted clique.

Let $(\tilde{x}, \tilde{y}) = (x_{[N]}/p, y_{[N]}/q)$ denote the strategies conditioned on playing on the first $N$ strategies. We claim that $(\tilde{x}, \tilde{y})$ must be an $\varepsilon'$-approximate equilibrium for the original game $G$, with $\varepsilon' = \frac{\varepsilon}{pq}$. To see this, suppose for contradiction that one of the players, say the row player, gains $\varepsilon'$ in $G$ by deviating to some strategy $e_\nu$. Consider “lifting” this to a new strategy $x'$ for $G'$ (i.e., in the strategy $x'$ the row player plays $e_{N+1}$ with probability $1 - p$, and $e_\nu$ with probability $p$). The change in payoff the row player obtains in $G'$ by switching from $x$ to $x'$ can be written as

$$
p(q\varepsilon' + (1 - q) \cdot 0),
$$

(5)

where the $q\varepsilon'$ term is what the row player gains from when the column player plays on the first $N$ strategies, and the other term is 0 since, when the column player plays on $N + 1$ the row player gets the same payoff on all the first $N$ strategies. As $(x, y)$ is an $\varepsilon$-approximate equilibrium in $G'$, (5) must be bounded by $\varepsilon$ and hence

$$
\varepsilon' \leq \frac{\varepsilon}{pq}.
$$

(6)

Now the same argument as in the first part of the proof of Lemma 3.8 gives that

$$
\varepsilon \geq p(q(\lambda - 1) + p(1 - q)(1 - 0)) \quad \text{(row player’s incentive to deviate)}
$$

$$
= p(1 - 11q/10) \quad \text{(by choice of $\lambda$)}
$$

$$
\geq p(1 - 11p/10).
$$

This quadratic inequality in $p$ implies that either $p \leq \varepsilon + O(\varepsilon^2)$ or $11p/10 \geq 1 - \varepsilon - O(\varepsilon^2)$. The first possibility is ruled out by our assumption, therefore $p > \frac{10}{11}(1 - \varepsilon - O(\varepsilon^2))$, and similarly $q > \frac{10}{11}(1 - \varepsilon - O(\varepsilon^2))$.

It is easy to see that the value of $(\tilde{x}, \tilde{y})$ must be at least 1/10 because $(x, y)$ is an $\varepsilon$-equilibrium for $G'$. By the choice of parameters, if $(\tilde{x}, \tilde{y})$ is also a $(4\varepsilon)$-approximate equilibrium for $G$ then we can reconstruct the hidden clique and we are done. But this follows easily from (6).
5 Small support equilibria

In this section, we show hardness of finding an ε-approximate Nash equilibrium with small (logarithmic) support when one exists, even for ε close to $\frac{1}{2}$. Note that an ε-approximate Nash equilibrium for two-player $n'$-strategy games with support at most $O(\log n'/\varepsilon)$ is guaranteed to exist by the algorithm of Lipton et al. [LMM03]. Here we consider approximate equilibria with smaller (but still logarithmic) support. Also, note that this is tight, since for $\varepsilon = \frac{1}{2}$, we have the simple algorithm of [DMP09], which gives a $\frac{1}{2}$ equilibrium of support 3.

Our reduction for small support equilibria involves the following construction, which is very similar to the earlier one.

**Reduction 5.1.** Given a graph $G = (V, E)$ with adjacency matrix $A$, construct a game $G = (M_{row}, M_{col})$ as follows.

$$M_{row} = \begin{pmatrix} \alpha A & 0 & \ldots & 0 \\ B \\ \vdots \\ B \end{pmatrix} \quad M_{col} = \begin{pmatrix} \alpha A & B^T & \ldots & B^T \\ 0 \\ \vdots \\ J - R \end{pmatrix}, \quad (7)$$

where $B$ is an $N_1 \times n$ matrix whose entries are i.i.d. $\{0, 1\}$ variables with expectation $\beta$. As in Reduction 3.2, $N_1 = n^c$ where $c = (c_2 + 1) \log 1/\beta$ and $c_2$ is the constant from Lemma 3.1.

Each payoff matrix of (7) contains $N_2$ identical copies of $B$, and $R$ is an $N_1 N_2 \times N_1 N_2$ uniformly random $\{0, 1\}$ matrix.

**Theorem 5.2.** For every $\eta > 0$ there exists $C > 0$ such that finding a $(\frac{1}{2} - \eta)$-equilibrium with support at most $(\log n)/2$ is as hard as finding a hidden clique of size $C \log n$ in $G(n, \frac{1}{2})$.

**Proof.** Given a graph $G$ from $G(n, \frac{1}{2})$ (possibly with a hidden clique), construct the game $G$ as in Reduction 5.1 with the following parameters: let $\alpha = \frac{1}{2} + \eta/8$, let $\beta = \alpha + (\frac{1}{2} - \eta) - \eta^2/8 = 1 - \frac{7}{8}\eta - \eta^2/8$. We choose the dimension $N_2$ as $N_2 = n^{c'}$, where $c'$ is chosen to satisfy $(\eta^2/8)^2 c' = 4c$. Since $c = (c_2 + 1) \log 1/\beta = \Theta(\eta)$ we have that $c' = \Theta(1/\eta^3)$. We choose the density $C$ of the hidden clique to be $C = c'/2 + 1$.

Note that the number of strategies is $n + N_1 N_2 = n + n^{c'+c}$, so that we are looking for an equilibrium with support at most $\frac{1}{2} \log (n + n^{c'+c}) = C' \log n$ for some $c'/2 \leq C' \leq c'/2 + 1$ (assuming $\eta$ is sufficiently small).

The completeness follows easily. Suppose $G$ contains a hidden clique of size $C \log n > C' \log n$. Then if both players play uniformly over the same subset of $C' \log n$ clique vertices, they both achieve reward $\alpha$. The probability that, say, the row player can gain $\frac{1}{2} - \eta$ (i.e. get payoff $\alpha + \frac{1}{2} - \eta = \beta + \eta^2/8$) by deviating to some row in $B$ (note that he can only deviate to rows in copies of $B$) is by the Chernoff bound Lemma 2.1 and a union bound at most

$$N_1 e^{- (\eta^2/8)^2 C' \log n} = n^{c - (\eta^2/8)^2 C'} \leq n^{c - (\eta^2/8)^2 c'/2} = n^{-c}.$$

Now, for the soundness, consider any $(\frac{1}{2} - \eta)$-equilibrium $(x, y)$. Let us first show that both players must have most of their probability concentrated in the $\alpha A$ block. Let $p = \|x_{[n]}\|$ and $q = \|y_{[n]}\|$ (the probabilities that each player plays in the first $n$ rows/columns). Let us consider the two player’s incentive to deviate. In the $\alpha A$ block, the row player achieves at most payoff $\alpha$,
and can achieve payoff \( \beta - o(1) \) by playing uniformly over all rows in \( B \) (w.h.p. this is true for all distributions over columns in \([n]\)). In particular, there exists at least one row in \( B \) in which the row player can achieve this value. Now consider the right hand side of the payoff matrix. Let \( \lambda \in [0, 1] \) be the payoff that the row player receives in \( R \) (thus, the column player receives \( 1 - \lambda \) here). For any row in \( B \), there are \( N_2 \) corresponding rows in \( R \) (one corresponding to each copy of \( B \)). Since the column player’s support is at most \( C' \log n \), the probability that regardless of the column player’s choice of support, there will be at least one row among these that has all 1’s in the corresponding positions is at least

\[
1 - n^{C' \log n (1 - 2^{-C' \log n} N_2)} \geq 1 - n^{C' \log n \exp(-2^{-C' \log n N_2})} \\
= 1 - n^{C' \log n e^{-n^{-C'/2}}} \\
\geq 1 - n^{C' \log n e^{-n^{C'/2} - 1}}.
\]

Thus, w.h.p. for every row in \( B \) and every possible strategy for the column player (up to the restriction on support size), there is a row in \( R \) corresponding to the correct row in \( B \) s.t. the row player would achieve payoff 1 in \( R \) (by deviating to this row). In particular, this is true for the row in \( B \) where the row player can achieve value \( \beta - o(1) \) (as before, we will ignore this \( o(1) \)). To summarize, by deviating, the row player can gain at least

\[
qp(\beta - \alpha) + (1 - q)(1 - (1 - p)\lambda).
\]

Similarly, the column player’s incentive to deviate is at least

\[
pq(\beta - \alpha) + (1 - p)(1 - (1 - q)(1 - \lambda)).
\]

On average, the two players’ incentive to deviate is at least

\[
qp(\beta - \alpha) + \frac{1}{2}((1 - p) + (1 - q)) - \frac{1}{2}(1 - p)(1 - q) = pq(\beta - \alpha) + \frac{1}{2}(1 - pq),
\]

and since this incentive is at most \( \frac{1}{2} - \eta \), we have

\[
pq(\beta - \alpha - \frac{1}{2}) + \frac{1}{2} \leq \frac{1}{2} - \eta, \tag{8}
\]

or

\[
pq \geq \eta/(\frac{1}{2} - (\beta - \alpha)) = \eta/(\eta + \eta^2/8) > 1 - \eta/8.
\]

Now it remains to bound the conditional value \( w \) that is achieved in the \( \alpha A \) block. This we can do using the same analysis as above, but substituting \( w \) for \( \alpha \). Making this substitution in (8) and solving for \( w \) we have

\[
w \geq \eta/pq + \beta - \frac{1}{2} = \eta/pq + \frac{1}{2} - 7\eta/8 - \eta^2/8 \\
\geq \frac{1}{2} + \eta/8 - \eta^2/8 \\
= \alpha(1 - \eta^2/(4 + \eta)) \geq \alpha(1 - \eta^2/4).
\]

We are now in a position to apply Lemma \ref{lem:main-lemma}. As stated Lemma \ref{lem:main-lemma} only applies to Reduction \ref{red2} and not the present reduction but it can be verified that it works also in this case (what is needed is that the size of \( B \) is the same, and the presence of an approximate equilibrium with most mass in \( A \) and good value in \( A \)). We have \( t = \eta/8 \) and \( s = \eta^2/4 \) which is easily checked to satisfy the condition \( 1 - t - 3\sqrt{s}/2 \geq \alpha + (\frac{1}{2} - \eta) \). Thus we conclude the existence of a dense bipartite subgraph which, as before, allows us to reconstruct the hidden clique.
Note that we have a much smaller gap between the completeness and hardness above than in the other problems we have considered. In particular, we do not claim that finding a \( \frac{1}{2} - \eta \)-equilibrium with small support is hard even when an exact equilibrium with small support exists. However, modifying parameters in the above proof, such hardness can be shown for a smaller additive approximation:

**Theorem 5.3.** For every \( \eta > 0 \) there exists \( C > 0 \) such that finding a \( (\frac{1}{4} - \eta) \)-equilibrium with support at most \( O(\log n) \) in a two-player game which admits a pure Nash equilibrium is as hard as finding a hidden clique of size \( C \log n \) in \( G(n, \frac{1}{2}) \).

### 6 Computing approximate pure Bayes-Nash equilibrium

Bayesian games model the situation where the players’ knowledge of the world is incomplete. In this paper we focus on Bayesian games with two players, but the results generalize to an arbitrary number of players. More details on Bayesian games can be found in most Game Theory textbooks, for example in [PT91].

In a Bayesian game the payoff of the players depends on the state of the world in addition to the players’ strategies. In a situation with two players, the row player and the column player, each player is presented with a signal, called type, about the state of the world \( \theta_{row} \in \Theta_{row} \) and \( \theta_{col} \in \Theta_{col} \), respectively. The types are distributed according to some joint distribution \( \mathcal{P} \) and are not necessarily independent. The types determine the payoff matrices \( M_{row}(\theta_{row}, \theta_{col}) \) and \( M_{col}(\theta_{row}, \theta_{col}) \). Denote the set of rows and columns in this matrix by \( S_{row} \) and \( S_{col} \), respectively. Each player chooses an action \( s_{row} \in S_{row} \) and \( s_{col} \in S_{col} \) from their respective set of actions. The payoff function of the first player is thus

\[
u_{row}(s_{row}, s_{col}, \theta_{row}, \theta_{col}) = M_{row}(\theta_{row}, \theta_{col}) s_{row} s_{col} \in [0, 1].
\]

The payoff function \( u_{col} \) is defined similarly. The payoff matrices, that depend on the players’ types, as well as the distribution on types is known to the players ahead of the game.

A pure strategy for the row player in a Bayesian game is a function (that by a slight abuse of notation) we denote by \( s_{row} : \Theta_{row} \rightarrow S_{row} \) that for each type \( \theta_{row} \) as observed by row player associates a strategy \( s_{row}(\theta_{row}) \) that the player chooses to execute. A pure strategy \( s_{col} : \Theta_{col} \rightarrow S_{col} \) is defined similarly.

Denote by \( \mathcal{P}_{\theta_{row}} \) the distribution on player column player’s types \( \theta_{col} \) conditioned on the type \( \theta_{row} \) being observed. For a pair of pure strategies \( (s_{row}, s_{col}) \) the payoff function of the row player is given by

\[
p_{row}(\theta_{row}) = \frac{\mathbb{E}}{\theta_{col} \sim \mathcal{P}_{\theta_{row}}} [u_{row}(s_{row}(\theta_{row}), s_{col}(\theta_{col}), \theta_{row}, \theta_{col})].
\]

A pure strategy Nash equilibrium in a Bayesian game, is a pair of functions \( s_{row}, s_{col} \) such that for all types observed, neither player has an incentive to deviate from his current strategy. In other words, for each \( \theta_{row} \), and for each \( s'_{row} \in S_{row} \),

\[
p_{row}(\theta_{row}) \geq \frac{\mathbb{E}}{\theta_{col} \sim \mathcal{P}_{\theta_{row}}} [u_{row}(s'_{row}, s_{col}(\theta_{col}), \theta_{row}, \theta_{col})],
\]

and a similar condition holds for \( p_{col} \).

Since a pure Nash equilibrium need not exist in non-Bayesian games, it need not exist in Bayesian games either. Moreover, while verifying whether a non-Bayesian two player game has a pure Nash equilibrium is trivial, verifying whether a pure Bayesian Nash equilibrium exists is NP-hard [CS03]. Furthermore, as the example in [CS03] demonstrates, this problem remains hard even when the distribution on types is uniform and the payoff does not depend on the players’ types.
A pure \(\varepsilon\)-Bayesian Nash equilibrium (\(\varepsilon\)-BNE) is defined similarly to an \(\varepsilon\)-Nash equilibrium. For each observed type \(\theta_{\text{row}}\), the incentive to deviate should be bounded by \(\varepsilon\):

\[
p_{\text{row}}(\theta_{\text{row}}) > \frac{1}{2}\mathbb{E}_{\theta_{\text{col}} \sim \mathcal{P}_{\theta_{\text{row}}}}[u_{\text{row}}(s'_{\text{row}}, s_{\text{col}}(\theta_{\text{col}}), \theta_{\text{row}}, \theta_{\text{col}})] - \varepsilon.
\]

A similar requirement should hold for the column player.

We show that for general distributions on types and for some small constant \(\varepsilon\), finding a pure \(\varepsilon\)-BNE in games where a pure BNE exists is still NP-hard. On the other hand, we also show that if the distribution on the players’ types is uniform, whenever a pure BNE exists, a pure \(\varepsilon\)-BNE can be found in quasi-polynomial time.

### 6.1 General distributions on types

We show that for some constant \(\varepsilon\), determining whether a pure strategy \(\varepsilon\)-Bayes Nash equilibrium exists is NP-hard. Specifically, \(\varepsilon = 0.004\) suffices. We prove:

**Theorem 6.1.** Let \(\varepsilon = 0.004\). Then given a Bayesian game that admits a pure BNE, it is NP-hard to find a pure \(\varepsilon\)-BNE for the game. Moreover, it is NP-hard to solve the promise problem of distinguishing games that admit a pure BNE from games that do not admit a pure \(\varepsilon\)-BNE.

**Proof.** We give a reduction from the problem of 3-coloring 4-regular graphs, which is known to be NP-complete [Dai80]. Let \(G(V, E)\) be a 4-regular graph with \(|V| = n\). The edges of \(G\) can be properly colored with 5 colors using Vizing’s algorithm. In other words, we can compute a coloring \(c : E \rightarrow \{1, \ldots, 5\}\) such that for every two edges \(e_1, e_2\) incident to the same vertex, \(c(e_1) \neq c(e_2)\).

We now design a Bayesian game such that:

- if \(G\) is 3-colorable, then the game admits a pure BNE;
- if \(G\) is not 3-colorable, then the game admits no pure \(\varepsilon\)-BNE.

The type of each of the players corresponds to a vertex in the graph, thus \(\Theta_{\text{row}} = \Theta_{\text{col}} = V\). The distribution on types is such that with probability 4/5, \((\theta_1, \theta_2)\) is a random edge in \(E\); with probability 1/5, \((\theta_1, \theta_2) = (\theta, \theta)\) is the same random vertex in \(V\). We note that in this example there is a high degree of correlation between the types of the two players.

Each player has 6 strategies available to him: \(S_{\text{row}} = S_{\text{col}} = \{1, 2, 3\} \times \{0, 1\}\). The first coordinate of \(s_{\text{row}}(v)\) should be thought of as the “color” assigned by player \(A\) to vertex \(v\), while the second coordinate is either “head” or “tails”, the use of which will be explained later. We denote the first coordinate by \(s_{\text{row}}(v)_1 \in \{1, 2, 3\}\) and the second by \(s_{\text{row}}(v)_2 \in \{0, 1\}\).

The payoff functions are defined as follows (\(s_{\text{row}}\) and \(s_{\text{col}}\) stand for \(s_{\text{row}}(\theta_{\text{row}})\) and \(s_{\text{col}}(\theta_{\text{col}})\), respectively):

| \(\theta_{\text{row}} \leq \theta_{\text{col}}\) | \(s_{\text{row}}(v)_1 \leq (s_{\text{col}})_1\) | \(s_{\text{row}}(v)_2 \leq (s_{\text{col}})_2\) | \(u_{\text{row}}\) | \(u_{\text{col}}\) |
|---|---|---|---|---|
| yes | yes | yes | 1 | 1 |
| yes | no | yes | 0.64 | 0 |
| yes | no | no | 0 | 0.64 |
| no | no | no | 1 | 1 |
| no | yes | yes | \(0.01 \times 2^{c(\theta_{\text{row}}, \theta_{\text{col}})}\) | 0 |
| no | yes | no | \(0.01 \times 2^{c(\theta_{\text{row}}, \theta_{\text{col}})}\) | |

In other words, the first coordinate of the strategy represents vertex color. The players are rewarded for producing a consistent 3-coloring: for the same vertex \(\theta\) the colors \((s_{\text{row}}(\theta))_1\) and
\((s_{\text{col}}(\theta))_1\) should match; for different vertexes connected by an edge the colors \((s_{\text{row}}(\theta_{\text{row}}))_1\) and \((s_{\text{col}}(\theta_{\text{col}}))_1\) should differ. If these conditions are satisfied, both players are rewarded with a payoff of 1. If a certain edge or vertex fails to satisfy the conditions, the games becomes a zero-sum games that depends on the second coordinate of the players’ strategies. The payoff can take values of 0.02, 0.04, 0.08, 0.16, 0.32 for edge pairs \((\theta_{\text{row}}, \theta_{\text{col}})\) and the value of 0.64 for vertex pairs \((\theta, \theta)\). What makes these values interesting is that no combination of these values with coefficients of \(-1, 0, +1\) adds up to less than 0.

If the graph \(G\) admits a 3-coloring \(C : V \to \{1, 2, 3\}\), then the pure strategy \(s_{\text{row}}(v) = s_{\text{col}}(v) = (C(v), 0)\) yields the optimal possible payoff of 1 for both players, and thus is a pure BNE.

On the other hand, suppose that \(G\) is not 3-colorable. Let \(s_{\text{row}}(v), s_{\text{col}}(v)\) be a set of pure strategies that is an \(\epsilon\)-BNE. Denote the expected payoff functions under these strategies by \(u_{\text{row}}(v)\) and \(u_{\text{col}}(v)\). If the row player deviates in her strategy from \((s_{\text{row}}(v)_1, s_{\text{row}}(v)_2)\) to \((s_{\text{row}}(v)_1, 1 - s_{\text{row}}(v)_2)\) her payoff only changes for type pairs where the conditions are not satisfied. Let us denote this change by \(\Delta_{\text{row}}(v)\). The contribution of each edge \((v_{\text{row}}, v_{\text{col}})\) to \(\Delta_{\text{row}}(v_{\text{row}})\) and \(\Delta_{\text{col}}(v_{\text{col}})\) cancels out, and hence, summing over all edges,

\[
\sum_{v \in V} (\Delta_{\text{row}}(v) + \Delta_{\text{col}}(v)) = 0.
\]

By the way we designed our payoffs, the values of \(\Delta_{\text{row}}(v)\) and \(\Delta_{\text{col}}(v)\) are integer multiples of 0.004. Moreover, if at least one edge adjacent to \(v\) is not satisfied, then \(\Delta_{\text{row}}(v)\) cannot be equal to 0. Since \(G\) is not 3-colorable, it means that \(\Delta_{\text{row}}(v) \neq 0\) for at least one of the vertexes. By (9) this means that \(\Delta_{\text{row}}(v) > 0\) or \(\Delta_{\text{col}}(v) > 0\) and thus \(\Delta_{\text{row}}(v) \geq 0.004\) or \(\Delta_{\text{col}}(v) \geq 0.004\). This contradicts the assumption that \((s_{\text{row}}, s_{\text{col}})\) is an \(\epsilon\)-BNE.

\[\square\]

### 6.2 Uniform distribution on types

In this section we show that in the case where the distribution on types is uniform, a pure \(\epsilon\)-BNE can be computed in quasi-polynomial time. This contrasts with the previously noted fact from [CS03] that computing a pure BNE is NP-hard even in this special case. As for other quasi-polynomial time computable approximate equilibria we’ve considered, whose exact variants are NP-hard, this problem is also as hard as Hidden Clique:

**Theorem 6.2.** For every \(\eta > 0\), finding a \((\frac{1}{4} - \eta)\)-approximate pure BNE in a two-player Bayesian games with uniformly distributed types and in which a pure BNE exists is as hard as finding a hidden clique of size \(C\log n\).

**Proof.** This follows immediately from Theorem 5.3. Let \(M_{\text{row}}\) and \(M_{\text{col}}\) be as in Reduction 5.1 with parameters set in order to achieve the \(\frac{1}{4} - \eta\)-hardness of Theorem 5.3. Consider the Bayesian game in which both players have exactly \(C\log n\) types,

the distribution over types is uniform, and the payoff matrices for each player are always the same \(M_{\text{row}}\) and \(M_{\text{col}}\) as above. Note that when there is a hidden clique, the following is an pure BNE: choose a subset \(S\) of \(C\log n\) clique vertices, and let each player play according to a one-to-one mapping from their type set to \(S\). On the other hand, it is easy to see that every pair of pure strategies for the Bayesian game corresponds to mixed strategies for the original game, where the incentive to deviate for, say, the row player, is the expected incentive to deviate in the Bayesian game (over all choices of types for the row player). In particular, if a player always has incentive at most \(\frac{1}{4} - \eta\) to deviate in the Bayesian game, their incentive will be at most \(\frac{1}{4} - \eta\) in the original game, and so by Theorem 5.3 we can recover the hidden clique. \[\square\]
We also note that our result generalizes to the case when the distribution on types is a product distribution, i.e. when $\theta_{\text{row}}$ is independent from $\theta_{\text{col}}$. To simplify the presentation we further assume that the type space is of equal size for both players, i.e. $|\Theta_{\text{row}}| = |\Theta_{\text{col}}| = k$. We prove:

**Theorem 6.3.** In a two-player Bayesian game, suppose that the types are distributed uniformly on the space $\Theta_{\text{row}} \times \Theta_{\text{col}}$, and that $|\Theta_{\text{row}}| = |\Theta_{\text{col}}| = k$, and $|S_{\text{row}}| = |S_{\text{col}}| = n$. Assuming that a pure BNE exists, we can find a pure $\varepsilon$-BNE in time $n^{O((\log n + \log k)/\varepsilon^2)}$.

**Remark 6.4.** The assumption in Theorem 6.3 can be relaxed to a pure $(\varepsilon/2)$-BNE equilibrium existing (instead of an actual equilibrium).

**Proof.** The proof is similar in spirit to the quasi-polynomial $\varepsilon$-Nash algorithm of [LMM03], but some additional work is needed. We first (approximately) guess the payoffs and the allowed strategies for both players for all possible types. We then use linear programming to produce a (not necessarily pure) $(3\varepsilon/4)$-BNE. We then sample from this approximate non-pure BNE to obtain a pure $\varepsilon$-BNE.

For simplicity, denote $\Theta_{\text{row}} = \Theta_{\text{col}} = \{1, \ldots, k\}$ and $S_{\text{row}} = S_{\text{col}} = \{1, \ldots, n\}$. Let $s_{\text{row}}: \Theta_{\text{row}} \rightarrow S_{\text{row}}$, $s_{\text{col}}: \Theta_{\text{col}} \rightarrow S_{\text{col}}$ be a pair of pure equilibrium strategies (that we assume exist). Let $p_{ij}^{\text{row}}$ and $p_{ij}^{\text{col}}$ be the corresponding payoff values. In other words, $p_{ij}^{\text{row}}$ is the payoff the row player gets when his type is $i \in \{1, \ldots, k\}$ and he plays strategy $j \in \{1, \ldots, n\}$. The equilibrium assumption is that for all $i$,

$$p_{ij}^{\text{row}} = \max_j p_{ij}^{\text{row}},$$

and a similar condition holds for $p_{ij}^{\text{col}}$. We first claim that we can recover all the values of $p_{ij}^{\text{row}}$ and $p_{ij}^{\text{col}}$ within an error of $\varepsilon/4$ with probability $> n^{-O((\log nk)/\varepsilon^2)}$.

**Claim 6.5.** There is a polynomial time algorithm that with probability $> n^{-O((\log nk)/\varepsilon^2)}$ outputs values $q_{ij}^{\text{row}}$, $q_{ij}^{\text{col}}$ such that for all $i, j$, $|q_{ij}^{\text{row}} - p_{ij}^{\text{row}}| < \varepsilon/8$ and $|q_{ij}^{\text{col}} - p_{ij}^{\text{col}}| < \varepsilon/8$.

**Proof.** We show how to approximate $p_{ij}^{\text{row}}$ well with probability $> n^{-O((\log nk)/\varepsilon^2)}$. The claim follows by approximating $p_{ij}^{\text{row}}$ and $p_{ij}^{\text{col}}$ independently. Pick a subset of $m = \lceil (40 \log\log nk)/\varepsilon^2 \rceil$ of the column player’s types $t_1, \ldots, t_m \in \{1, \ldots, k\}$. For each type $t_r$ guess the column player’s strategy $s_r$ on this type. With probability $n^{-m}$ we correctly guess all strategies, i.e. $s_r = s_{\text{col}}(t_r)$ for all $r$. Set

$$q_{ij}^{\text{row}} = \frac{1}{m} \sum_{r=1}^m u_{\text{row}}(j, s_r, i, t_r).$$

In other words, we calculate an estimate of the expected payoff $p_{ij}^{\text{row}}$ using only the value at the types we’ve guessed. By Hoeffding’s Inequality, for each $(i, j)$ the probability

$$\mathbb{P}[|q_{ij}^{\text{row}} - p_{ij}^{\text{row}}| \geq \varepsilon/8] \leq 2 \cdot \exp(-m\varepsilon^2/32) < 1/(4nk).$$

The claim follows by union bound. \hfill \Box

Allowing for a blow-up of $n^{O((\log nk)/\varepsilon^2)}$ in running time, we may assume from now on that the correct values of $q_{ij}^{\text{row}}$ and $q_{ij}^{\text{col}}$ had been computed (up to an error of $\varepsilon/8$), since in the end we can check whether the set of pure strategies obtained is a $\varepsilon$-BNE.

Next, we formulate a linear program that obtains a $(3\varepsilon/4)$-BNE with payoff values close to $q_{ij}^{\text{row}}, q_{ij}^{\text{col}}$. The variables of the program are $X_{ij}^{\text{row}}$ and $X_{ij}^{\text{col}}$, where $X_{ij}^{\text{row}}$ corresponds to the probability that the row player plays strategy $j$ on type $i$. For each type $i$ let

$$M_i^{\text{row}} := \max_j q_{ij}^{\text{row}}$$
be the maximum possible payoff the row player can attain on type $i$ under payoffs $q_{ij}^\text{row}$. We only allow $X_{ij}^\text{row}$ to be non-zero when the corresponding payoff $q_{ij}^\text{row} > M_i^\text{row} - \varepsilon/8$. This guarantees that the solution we obtain is a $(3\varepsilon/4)$-BNE. In addition, we enforce the payoffs to be close to $q_{ij}^\text{row}$. For each $i, j$ we have the constraint

$$|q_{ij}^\text{row} - \frac{1}{k} \sum_{y,z} X_{yz}^\text{col} \cdot u_{irow}(j, z, i, y)| < \varepsilon/4,$$

and a similar condition on the $X^\text{row}$'s. This linear program is feasible since the pure BNE we assumed exists is a solution to it. Denote the resulting expected payoffs by $v_{ij}^\text{row}$ and $v_{ij}^\text{col}$.

The solution thus obtained is a $(3\varepsilon/4)$-BNE. To see this, we actually observe that the equilibrium is well supported: for each type $i$, each strategy $j$ with $X_{ij}^\text{row} \neq 0$ the payoff $v_{ij}^\text{row} \geq M_i^\text{row} - 3\varepsilon/8 \geq \max_{j'} v_{ij'}^\text{row} - 5\varepsilon/8$.

To complete the proof we now obtain a set of pure strategies $s_{\text{row}}' : \Theta_{\text{row}} \to S_{\text{row}}$, $s_{\text{col}}' : \Theta_{\text{col}} \to S_{\text{col}}$ by sampling $j = s_{\text{row}}'(i)$ according to the probability distribution $X_{ij}^\text{row}$. Assuming $k = \Omega((\log(nk))/\varepsilon^2)$, once again by Hoeffding’s Inequality the payoffs will be $\varepsilon/8$-close to the payoffs $v_{ij}^\text{row}$, and thus the resulting game will be in an $\varepsilon$-BNE.

In the case when $k = O((\log(nk))/\varepsilon^2)$, i.e. the number of types is small, we can find the exact BNE by brute force, completing the proof of the theorem. \qed
