ABSTRACT

Atherosclerosis is a leading cause of worldwide morbidity and mortality whose management could benefit from novel targeted therapeutics. Nanoparticles are emerging as targeted drug delivery systems in chronic inflammatory disorders. To optimally exploit nanomedicines, understanding their biological behavior is crucial for further development of clinically relevant and efficacious nanotherapeutics intended to reduce plaque inflammation. Here, three clinically relevant nanomedicines, i.e., high-density lipoprotein ([S]-HDL), polymeric micelles ([S]-PM), and liposomes ([S]-LIP), that are loaded with the HMG-CoA reductase inhibitor simvastatin [S], were evaluated in the apolipoprotein E-deficient (Apoe−/−) mouse model of atherosclerosis. We systematically employed quantitative techniques, including in vivo positron emission tomography imaging, gamma counting, and flow cytometry to evaluate the biodistribution, nanomedicines’ uptake by plaque-associated macrophages/monocytes, and their efficacy to reduce macrophage burden in atherosclerotic plaques. The three formulations demonstrated distinct biological behavior in Apoe−/− mice. While [S]-PM and [S]-LIP possessed longer circulation half-lives, the three platforms accumulated to similar levels in atherosclerotic plaques. Moreover, [S]-HDL and [S]-PM showed higher uptake by plaque macrophages in comparison to [S]-LIP, while [S]-PM demonstrated the highest uptake by Ly6Chigh monocytes. Among the three formulations, [S]-PM displayed the highest efficacy in reducing macrophage burden in advanced atherosclerotic plaques. In conclusion, our data demonstrate that [S]-PM is a promising targeted drug delivery system, which can be advanced for the treatment of atherosclerosis and other inflammatory disorders in the clinical settings. Our results also emphasize the importance of a thorough understanding of nanomedicines’ biological performance, ranging from the whole body to the target cells, as well drug retention in the nanoparticles. Such systematic investigations would allow rational applications of nanomaterials, beyond cancer, facilitating the expansion of the nanomedicine horizon.

1. Introduction

Atherosclerosis is a chronic, systemic inflammatory disease of the large and medium-sized arteries, which can lead to life-threatening events such as myocardial infarction and stroke [1]. According to the World Health Organization, 17.5 million deaths per year, an estimated 31% of
all deaths worldwide, can be attributed to atherosclerotic cardiovascular diseases [2]. The initiation and progression of atherosclerotic lesions are currently understood to have a central inflammatory component in which immune cells, including inflammatory monocytes and macrophages, play key roles [3,4]. At early stages, elevated levels of circulating apolipoprotein B-containing lipoproteins induce focal expression of endothelial adhesion molecules [5], which promote the recruitment of inflammatory Ly6Chigh monocytes to the arterial wall [6]. Once adhered, monocytes transmigrate into the subendothelial space and differentiate into resident macrophages [4]. The continued accumulation of lipoproteins and immune cells, including macrophages, accelerates the development of focal lesions known as atherosclerotic plaques [7]. In advanced atherosclerosis, plaque-associated macrophages proliferate and secrete proinflammatory mediators, reactive oxygen species, and proteases which destabilize the plaque and aggravate the disease [8,9]. Additionally, recent preclinical [10] and clinical [11] work have identified cardiovascular events as key contributors to the aggravation of plaque inflammation, increasing secondary event’s risk [12]. Thus, silencing plaque inflammation by targeting monocyte/macrophage burden is a compelling disease management strategy.

Over the last few decades, extensive research has been conducted to explore the potential use of nanomaterials as novel drug delivery systems in cancer [13–17] and other inflammatory disorders [18,19]. While liposomes [20] have always been frontrunners, the nanomedicine field has also witnessed an exponential increase in the number of new nanomaterials [21,22], including polymeric micelles [23,24] and high-density lipoproteins (HDL) [25] as systems which have already matured up to the level of clinical application [23,26,27]. However, the majority of studies explore and focus on only one specific nanomaterial, mainly for tumor targeting [28], without comparing performance against other existing nanocarriers. Beyond cancer, more comprehensive investigations of these nanomaterials, covering drug-nanocarrier compatibility (i.e., loading efficiency, and drug retention and release) and in vivo performance (i.e., pharmacokinetics, tissue distribution, atherosclerotic plaque targeting and efficacy), are necessary. Understanding the factors that govern nanomedicines’ in vivo performance is critical to ensure rational optimization, adequate quality control, and potential early stage clinical translation [29,30].

3-Hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA) inhibitors, also known as statins, are the standard of care for patients with atherosclerotic cardiovascular diseases. Their oral application leads to reduced low-density lipoprotein (LDL) cholesterol blood levels, primarily by modulating hepatic LDL receptor expression [31]. Also, HMG-CoA inhibitors display pleiotropic effects at high doses, including anti-inflammatory and anti-proliferative activities [32,33]. In a clinical trial, high dose oral statin therapy was shown to reduce atherosclerotic inflammation, using 18F-fluorodeoxyglucose-positron emission tomography/computed tomographic imaging (FDG-PET/CT) in patients [34]. Moreover, in an atherosclerotic mouse model, Sparrow et al. showed that oral simvastatin, a frequently used HMG-CoA inhibitor, has anti-inflammatory and anti-atherosclerotic effects at a dose of 100 mg/kg, independent of its cholesterol-lowering properties [35]. However, increasing the oral statin standard dose in human is not possible because of the dose-dependent adverse effects such as myopathy and hepatotoxicity [36]. At the same time, orally administered statins undergo hepatic metabolism, which results in a very poor plaque bioavailability [37]. Therefore, intravenous nanocarrier-mediated targeting of HMG-CoA inhibitors to atherosclerotic plaques is an attractive approach to achieve enhanced anti-inflammatory and anti-atherosclerotic effects, as we have shown for simvastatin-loaded HDL ([S]-HDL) [38,39].

In this paper, we present a comprehensive comparative analysis of three established and clinically viable nanomedicines targeting the HMG-CoA inhibitor simvastatin ([S] to atherosclerotic plaques. The nanomedicines include [S]-HDL, [S]-N-(2-hydroxypropyl)-methacrylamide benzyl mPEG-b-(HPMAm-Bz)-based PEGylated polymeric micelles (mPEG-b-(HPMAm-Bz); [S]-PM), and [S]-PEGylated liposomes ([S]-LIP) (Fig. 1). We aimed to systematically investigate and compare the performance of the three [S]-nanomedicines in ApoE−/− mice with advanced atherosclerosis. To attain a thorough understanding of the in vivo behavior of the three platforms, we dual-labeled them with Zirconium-89 (89Zr) and the near-infrared dye Cy5.5. The 89Zr signal was exploited to provide a sensitive and quantitative assessment of their biodistribution and pharmacokinetics using noninvasive PET/CT imaging and gamma counting. The Cy5.5 signal was used to evaluate immune cell targeting in atherosclerotic plaques, blood, and spleen using flow cytometry. The efficacy of the three [S]-nanomedicines in ApoE−/− mice was quantitatively assessed by flow cytometry. [S]: simvastatin; HDL: high density lipoprotein; PM: polymeric micelles; LIP: liposomes; ApoE−/−: apolipoprotein E-deficient.

Fig. 1. Schematic of the [S]-nanomedicines and study design. [S]-HDL, [S]-PM, and [S]-LIP were evaluated in ApoE−/− mice with advanced atherosclerosis. To attain a thorough understanding of the in vivo behavior of the three platforms, we dual-labeled them with Zirconium-89 (89Zr) and the near-infrared dye Cy5.5. The 89Zr signal was exploited to provide a sensitive and quantitative assessment of their biodistribution and pharmacokinetics using noninvasive PET/CT imaging and gamma counting. [S]: simvastatin; HDL: high density lipoprotein; PM: polymeric micelles; LIP: liposomes; ApoE−/−: apolipoprotein E-deficient.

2. Materials and methods

2.1. Materials and radiochemistry

1,2-Dipalmitoyl-sn-glycerol-3-phosphocholine (DPPC), N-(carboxymethoxy-PEG2000)-1,2-distearyl-sn-glycerol-3-phosphoethanolamine (DSPE-PEG2000), cholesterol, 1-myristoyl-2-hydroxy-sn-glycerophosphocholine (MHPC), and 1,2-dimyristoyl-sn-glycerol-3-phosphatidylincholine (DMPC) were purchased from Avanti Polar Lipids. The copolymers (methoxy poly(ethylene glycol)-b-(N-(2-benzoxyloxypropyl) methacrylamide) (mPEG-b-(HPMAm-Bz)) and the amino-functionalized version, mPEG-b-p(HPMA-Bz-co-AEMAm), were synthesized by free radical polymerization, using mPEG2-BCPA as macroinitiator and HPMA-Bz as a monomer, as previously reported [40]. Briefly, the monomer and the macroinitiator were dissolved at a molar ratio of 200:1 in dried (over 4 Å molecular sieves) acetonitrile (Biosolve Ltd) at a final concentration of 300 mg/mL. The solution was flushed with nitrogen gas for 30 min and then immersed in a silicone bath at 70 °C for at least 17 h. Afterward, the solution was placed in cold diethyl ether to precipitate the formed polymer and centrifuged at 2600 × g for 15 min. The supernatant was discarded, and the pellet was re-dissolved in acetonitrile. This procedure was repeated three times, and the final product was dried under vacuum overnight at room temperature (RT) to remove the remaining organic solvent. For the synthesis of the
amine-functionalized copolymer, 2% (moles) of AEMAm, N-(2-ami-noethyl) methacrylamide hydrochloride, (relative to HPMA-Bz) was added to the reaction mixture and the reaction was conducted as described above. DSPE-Cyanine5 (Cy5.5) was purchased from SyMO-Chem BV while synthesis and Cy5.5 labeling of mPEG-b-p(HPMAm-Bz) were done according to a method reported before [40]. Simvastatin and simvastatin sodium salt were obtained from AK Scientific and Cayman Chemical, respectively. All other materials were purchased from Sigma-Aldrich unless otherwise stated.

Zirconium-89 ($^{89}$Zr) was produced at Memorial Sloan Kettering Cancer Center on a TR19/9 variable-beam energy cyclotron (Ebcio Industries Inc.) via the $^{89}$Y(p,n)$^{90}$Zr reaction and purified in accordance with the previously reported method [41]. Activity was measured using a CRC 15R dose calibrator (Capintec).

2.2. Characterization of mPEG-b-p(HPMA-Bz) copolymer

Gel Permeation Chromatography (GPC) was performed to determine the number average molecular weight (Mn), weight average molecular weight (Mw), and polydispersity (Mw/Mn) of the synthesized polymers. Two serial Plgel 5 μm MIXED-D columns (Polymer Laboratories) were used, and the run was performed in 10 mM LiCl DMF, at a flow rate of 1 mL/min and a column temperature of 65 °C. PEGs of narrow molecular weight distribution were used as standards. Samples were prepared at a concentration of 5 mg/mL in 10 mM LiCl DMF and allowed to dissolve for 30 min at 37 °C.

1H NMR spectrum of mPEG-b-p(HPMAm-Bz) was recorded using a Gemini 300 MHz spectrometer (Varian Associates Inc. NMR Instruments), using DMSO-d$_6$ as a solvent and the DMSO peak at 2.50 ppm as a reference. Chemical shifts of PEG-HPMA-Bz were assigned as described elsewhere [40]. The ratio between HPMA-Bz and mPEG was determined by the integral value of aromatic protons of HPMA-Bz (8.0 ppm, 2H, aromatic CH) divided by two, and the integral value of the methylene protons of mPEG (3.40–3.60 ppm, 448H, O-CH$_2$-CH$_2$) divided by 448 (average number of protons per PEG chain, Ms = 5000 g/mol). The average number molecular weight (Mn) of the block copolymer was determined as follows:

$$\text{Mn} = \frac{\text{integral at 8.0 ppm} \times \text{molar mass of HMPA-Bz}}{\text{integral at 3.40-3.60 ppm}/448} + 5000 \text{ g/mol}$$

The copolymers used to prepare the [S]-PM, i.e. mPEG-b-p(HPMAm-Bz) and the amine-functionalized, mPEG-b-p(HPMAm-Bzco-AEMAm), were synthesized by free radical polymerization via a macroinitiator route [40]. Both copolymers show similar number-average molecular weight (Mn) ~ 22 KDa and PDI ~ 1.7 based on GPC and $^{1}$H NMR analyses (Supporting Figs. 1 and 2 and Supporting Table 1).

2.3. Assessment of simvastatin and simvastatin sodium salt activity

To assure that both simvastatin, used in [S]-HDL and [S]-PM, and simvastatin sodium salt, used in [S]-LIP, have equipotent pharmacological activity, we assessed their dose-dependent effects on macrophage proliferation (Supporting Fig. 3).

2.4. Formulation of simvastatin nanomedicines

Formulation of the HMG-CoA inhibitor simvastatin HDL ([S]-HDL) was done according to a method reported before [38,39]. In brief, simvastatin, DMPC, and MHP, in a weight % ratio of 14:78:8, respectively, were dissolved in a chloroform/methanol mixture (4:1 by volume) and a lipid film was prepared by rotary evaporation (Büchi Labortechnik) and dried under a nitrogen stream for 1 h until complete dryness. The lipid film was then hydrated with human apolipoprotein A1 (APOA1, isolated from human plasma) in PBS (APOA1 and phospholipids in a 1:9 weight ratio). The mixture was incubated at 37 °C until the film was completely hydrated. The lipid dispersion was subjected to ultrasonication to form [S]-HDL nanomedicine formulation.

To formulate HMG-CoA inhibitor liposomes ([S]-LIP), we used simvastatin provided as sodium salt, a water-soluble derivative that allows its entrapment in liposomes. Liposome preparation was modified from a method described previously [42]. Briefly, dipalmitoylphosphatidylcholine (DPPC), cholesterol, and DSPE-PEG2000, in a weight % ratio of 61.7:33.5:5, respectively, were dissolved in a chloroform/methanol mixture (4:1 by volume) in a round-bottom flask. A lipid film was prepared by evaporation of the solvents and subsequently hydrated with a solution of 5 mg/mL simvastatin (sodium salt) in PBS (5 mL). The mixture was then heated at 60 °C until the film was completely hydrated. To downsize the lipid dispersion, the lipid particles were subjected to multiple extrusion steps through polycarbonate membranes (Whatman, Nucleapore) with a final pore size of 100 nm using a Lipex extruder (Northern Lipids).

Preparation of HMG-CoA inhibitor HPMA-based polymeric micelles ([S]-PM) was done as described by Shi et al. [40]. Briefly, mPEG-b-p(HPMAm-Bz) copolymer (10 mg) and simvastatin (2 mg) were both completely dissolved in 0.5 mL tetrahydrofuran (THF). Then the polymer/drug mixture was slowly added dropwise to 2 mL of Milli-Q water while stirring to form [S]-PM. The mixture was then incubated for 48 h at RT to allow evaporation of THF.

[S]-HDL was washed with PBS at least three times using ultrafiltration units with a 50 kDa molecular weight cutoff (MWCO) (Sartorius Stedim Biotech SA). [S]-PM or [S]-LIP were purified with PBS using VivaFlow crossflow cassettes filtration units with a 100 kDa MWCO (Sartorius Stedim Biotech SA). All the three formulations were centrifuged at 4000 × g for 30 min to remove any aggregates. Finally, each formulation was filtered through a 0.22 μm nylon membrane filter (CellTreat Scientific Products).

2.5. Dual labeling of simvastatin nanomedicines

The [S]-nanomedicines were labeled with Cy5.5 to allow near-infrared fluorescence (NIRF) imaging and flow cytometry studies. Briefly, 0.5% of DSPE-Cy5.5 was incorporated into the lipid film of either [S]-HDL or [S]-LIP during the lipid film preparation (modified from [43]). For [S]-PM, 0.5% of Cy5.5-labeled mPEG-b-p(HPMAm-Bz) was added to the simvastatin/polymer mixture in THF before adding to Milli-Q water (modified from Shi et al. [40]).

To additionally label the nanomedicines with $^{89}$Zr for PET imaging and quantitative biodistribution assessment, a similar approach was followed as we previously reported [41,44]. Briefly, 0.5% of DSPE-desferrioxamine (DSPE-DFO) [41] was incorporated in the lipid film of [S]-HDL or [S]-LIP. For the polymeric micelles, to functionalize the polymer with DFO, a solution of the amine-functionalized copolymer mPEG-b-p(HPMAm-Bzco-AEMAm) (2.0 mg), p-isothiocyanatobenzoyl-DFO (Macroyclics) (40 μg, ~1 eq) and N,N-diisopropylethylamine (1.0 μL) in dimethylsulfoxide (0.21 mL) was heated at 40 °C for 8 h. The mixture was then allowed to cool down to RT. Water (1.8 mL) was added, and the resulting milky solution was concentrated by centrifugal filtration using a 10 kDa MWCO tube and washed three times with Milli-Q water (2 mL). The final retentate was dried under vacuum to
yield the DFO-modified polymer as a white solid (2.0 mg). The DFO-modified mPEG-b-p(HPMAm-Bz) was added at 5% of the total polymer weight to the formulation mix at the expense of non-modified mPEG-b-p(HPMAm-Bz). Subsequently, a PBS dispersion of the corresponding DFO-bearing nanomedicine formulation was reacted with [89Zr] Zr2(C2O4)3 at pH 7.1–7.4 for 1 h at 37 °C. The dispersion was allowed to cool down to RT, and the radiolabeled nanocarriers were purified by centrifugal filtration using 10 kDa MWCO filter tubes for [S]-HD, and 100 kDa MWCO filter tubes for [S]-LIP and [S]-PM. The radiochemical yield was > 80% with radiochemical purities > 95% for the three formulations.

2.6. Characterization

The mean particle size and polydispersity index (PDI) of the different [S]-nanomedicines used in this study were determined by dynamic light scattering using a Malvern NanoSeries Z-Sizer. The Zeta (ζ)-potential was determined using a PALS analyzer (Brookhaven Instruments Corp.) where [S]-nanomedicine samples were diluted in 10 mM HEPES buffer (pH 7.4) before measurements. The morphology of the nanomedicines was determined by transition emission microscopy (TEM). Briefly, the original PBS solvent was replaced by an ammonium acetate buffer and then mixed with 2% (wt/vol) sodium phosphotungstate (pH = 7.4) to negatively stain the [S]-nanomedicine. The solution was then cast dried on a nickel grid and imaged with a Hitachi H7650 TEM.

2.7. HPLC and radio-HPLC

Simvastatin concentrations in the different samples were determined as previously reported [39]. The simvastatin content of the nanocarriers or samples from drug release studies (described in the following section) was determined by HPLC, using a Prominence LC-20AB system (Shimadzu) equipped with a C18 column at a flow rate of 0.5 mL/min. The radiochemical purity of the [S]-nanomedicines was determined by size-exclusion high-performance liquid chromatography (SEC) using a Superdex 10/300 GL filter tubes for [S]-HDL, and 200 μL of PBS solution via the lateral tail vein.

2.10. Micro-PT/CT imaging

Twenty four hours after injecting the [89Zr]-[S]-nanomedicines (0.18 ± 0.03 mCi/animal), the animals (n = 3 per treatment type) were anesthetized with a mixture of isoflurane (Baxter Healthcare) and oxygen gas (2% for induction and 1% for maintenance), and scans were then obtained using an Inveon PET/CT scanner (Siemens Healthcare Global). Whole-body PET static scans recording a minimum of 50 million coincident events were performed with duration of 10–20 min. Whole body standard low-magnification CT scans were obtained with the x-ray tube set at a voltage of 80 kV and current of 500 mA. The CT scan was acquired using 120 rotational steps for a total of 220°, yielding an estimated scan time of 120 s with an exposure of 145 ms/frame. The counting rates in the reconstructed images were converted to activity concentrations (%ID/g) by use of a system calibration factor derived from the imaging of a mouse-sized water-equivalent phantom containing the radionuclide. Images were analyzed using Inveon Research Workplace software (Siemens Healthcare Global). Activity concentration was quantified by averaging the maximum values in at least 5 ROIs drawn on adjacent slices of the tissue of interest.

2.11. Pharmacokinetics and biodistribution

Apoe−/− mice (n ≥ 3 per [S]-nanomedicine type) were administered 26 ± 5 μCi [89Zr]/animal of the corresponding dual labeled [89Zr]/Cy5.5 [S]-nanomedicines at doses of 0.8 mg Cy5.5/kg and 60 mg simvastatin/kg (as in the therapeutic study). Blood was sampled (∼ 10–20 mL/each sample) at predetermined time points (30 min, 1, 2, 4, 8, and 24 h) after injection. After 24 h, the mice were euthanized and perfused with 30 mL PBS/mouse through cardiac puncture, and organs of interest (aorta, liver, spleen, kidneys, lungs, heart, and brain) were excised. The blood samples (at the different time points) and samples of other tissues were weighed, and their radioactivity content was quantified using Wizard 2470 Automatic Gamma Counter (Perkin Elmer). The values were corrected for [89Zr] decay and radioactivity concentration was calculated as a percentage of injected dose per gram of tissue (%ID/g).

[S]-nanomedicines biodistribution was also qualitatively assessed by NIRF imaging and autoradiography. Perfused tissue samples were placed on a thick black paper and imaged on a Xenogen IVIS Spectrum Preclinical Imaging System (Perkin Elmer). Fluorescence images were acquired with selected excitation and emission band-pass filters: for Cy5.5 λexc = 640 ± 18 nm, λem = 720 ± 10 nm. Exposure time for each image was 2 s. To assess the radionuclease distribution, tissues were placed on a film cassette against a phosphorimaging plate (BASMSM-2325, Fujifilm) for either 24 h (aortas) or 18 h (all other organs) at −20 °C. The plates were then read at a pixel resolution of 25 μm in a Typhoon 7000IP plate reader (GE Healthcare).

2.12. Flow cytometry

To study the uptake of [S]-nanomedicines by immune cells, we used flow cytometry protocols similar to what was previously reported [38,47]. Briefly, Apoe−/− mice (n = 4 per group, 18 weeks on HFD)
were injected with Cy5.5-labeled \([S]\)-nanomedicines at 0.8 mg Cy5.5/kg (at a dose of 60 mg/kg simvastatin). After 24 h, to prepare cells for flow cytometry, blood was collected by cardiac puncture into tubes with a 50 mM EDTA solution as an anticoagulant. Red blood cells (RBCs) were lysed using RBC lysis buffer (BD Biosciences). Afterward, animals were perfused with 30 mL PBS/mouse. The whole aorta, from the aortic root to the iliac bifurcation, and spleen were harvested. Single-cell suspensions were obtained as follows: aortas were diced and digested with a cocktail of enzymes, including 4.5 U/mL liberase TH (Roche), 60 U/mL hyaluronidase (Sigma-Aldrich), and 40 U/mL DNase (Sigma-Aldrich), in a 37 °C oven for 1 h while shaking. Then, tissue aggregates, extracellular matrix, and cell debris were removed by filtration. Spleens were also diced, and RBCs were removed using the same lysis buffer described above. To identify macrophages, monocytes, dendritic cells, neutrophils, and other immune cells, a cocktail of antibodies was used (antibodies, clones, and suppliers shown in Table S.2). Cy5.5 signal was detected on the Alexa700 channel.

In the efficacy study, we quantified the number of macrophages and Ly6Chigh monocytes in atherosclerotic plaques. Complete blood count was also performed as a control to assess the number of immune cells in the blood. Mice \((n = 8–10/group, 18 \text{ weeks on HFD})\) were administered the corresponding treatments (\([S]\)-nanomedicines, 60 mg/kg simvastatin; PBS, or oral simvastatin, 60 mg/kg) once every 72 h for a week (three injections in total). Mice were sacrificed 24 h after the last injection, and immune cells from aorta and blood were isolated and quantified. For both the targeting study and the efficacy study, we adopted a strict flow cytometry protocol by running ‘fluorescence minus one’ (FMO) controls to precisely gate the right cell population. In an FMO control stain sample, all reagents used in a given multicolor sample are included except the reagent with which the exact cell population is to be determined. All samples were measured on an LSRII (BD Biosciences) flow cytometer, and results were analyzed with FlowJo (Tree Star) software.

Serum from animals in the efficacy study was subjected to a biochemical analysis (ALX Laboratories, NY) to determine typical blood biochemistry constituents, including cholesterol and triglycerides, and toxicity markers like alanine transaminase.

### 2.13. Statistical analysis

Statistical analysis was performed using Prism (GraphPad), and data are expressed as a mean ± standard error of the mean. Differences between groups were assessed by one-way analysis of variance (ANOVA) followed by a post hoc test (Bonferroni’s test) for multiple comparisons. \(* P \leq 0.05; ** P \leq 0.01; *** P \leq 0.001\) A value of \(P < 0.05\) was considered statistically significant.

### 3. Results and discussion

The aim of this study was to target HMG-CoA in atherosclerotic plaques by simvastatin-loaded nanomedicines and to understand the...
parameters that control their in vivo performance. Liposomes were included as they are often regarded as the gold standard nanomedicine drug delivery system and were the first to make clinical translation [20,43]. Additionally, liposomes have been shown to successfully target atherosclerotic plaques in rabbits [43,48] and humans [49]. HDL, a natural self-assembled nanocarrier, has an intrinsic affinity to plaque macrophages in different atherosclerosis animal models [44,50]. The natural targeting ability of HDL and the possibility to incorporate hydrophobic compounds in its core makes it an attractive platform for drug delivery [51]. HPMO block copolymer-based micelles were shown to improve the retention of hydrophobic chemotherapeutic drugs in their matrix [52–54], offering effective targeted drug delivery to tumors and inflammatory sites [53,55,56]. However, they have not yet been evaluated in atherosclerosis. Here, we explored their ability to target atherosclerotic plaques for the first time and compared their performance with previously assessed HDL and liposomal formulations.

3.1. Preparation and characterization of simvastatin nanomedicines

[S]-HDL was prepared by ultrasonication, a well-established method to encapsulate hydrophobic drugs in HDL nanoparticles [57,58]. [S]-LIP was prepared using a more water-soluble derivative, i.e., simvastatin (sodium salt). [S]-PM was formulated by dropping a THF solution of the polymer and simvastatin into water followed by evaporation of THF, a method that was previously used to encapsulate hydrophobic drugs [52,59].

DLS analysis showed that the mean particle sizes (Z-average) of the three [S]-nanomedicines were different and none of them was larger than 100 nm. [S]-HDL possessed the smallest mean diameter (~50 nm) with a PDI ~ 0.22 (Fig. 2A and Table 1). Analysis of [S]-HDL by TEM showed the typical discoidal shape of HDL nanoparticles as reported before (38) (Fig. 2B). DLS analysis showed that [S]-PM and [S]-LIP had larger mean diameters of ~80 and ~95 nm, respectively (Fig. 2A and Table 1). Both formulations showed a low PDI ~ 0.1 (Table 1). TEM images of [S]-PM and [S]-LIP showed spherical particles (Fig. 2B). The zeta (ζ) potential of the three [S]-nanomedicines was negative in 10 mM HEPES buffer (pH 7.4), ranging from −5 mV for [S]-PM to −15 mV for both the liposomal and HDL formulations (Table 1). All the three [S]-nanomedicines had high simvastatin entrapment efficiency (> 60%) as shown in Table 1.

3.2. Drug release kinetics in serum

The extent and rate of drug release while nanocarriers circulate in the bloodstream is an important factor which can strongly affect a drug-loaded nanocarrier’s targeting efficiency and resulting therapeutic efficacy. The release kinetics of the three simvastatin nanoformulations in 90% serum at 37 °C, mimicking physiological conditions, was analyzed. Using size exclusion chromatography, we separated the nanocarrier from the serum proteins, and then analyzed the simvastatin content in each fraction (Supporting Fig. 4). The release kinetics of simvastatin from [S]-HDL was similar to that of [S]-LIP but much more rapid than [S]-PM (Fig. 2C). By the end of the 24 h incubation period, ~50% of the simvastatin from [S]-PM was released compared to ~80% and 90% in the case of [S]-LIP and [S]-HDL, respectively. The higher drug retention in case of [S]-PM can be explained by purposely designed physicochemical features that enhance hydrophobic and π-π stacking interactions [40,56]. In the case of [S]-LIP, simvastatin sodium salt was used to increase drug entrapment in the liposomal formulation. However, according to the manufacturer (Cayman), simvastatin (sodium salt) is sparingly soluble in aqueous solutions and probably also possess an affinity for the lipid bilayer, which may have resulted in drug leakage from the [S]-LIP upon interaction with serum proteins. Similarly, HDL has a dynamic structure, which could result in the exchange of lipid components upon interaction with other serum proteins, resulting in drug leakage [45].

3.3. Dual labeling of simvastatin nanomedicines

To better understand [S]-nanomedicines’ biodistribution and uptake by immune cells, we employed a dual-labeling strategy using 89Zr as a radioactive tag detectable by PET and gamma counting, and Cy5.5 for NIRF imaging and flow cytometry. 89Zr has a physical half-life of 78.4 h, making it suitable for long-circulating nanoparticles [41] and antibodies [60]. Additionally, PET imaging and gamma counting are sensitive, quantitative methods for evaluating [S]-nanomedicines’ pharmacokinetics, whole-body, and organ biodistribution, while flow cytometry allows assessment of immune cell specificity in atherosclerotic plaques and other tissues in a quantitative fashion. Both labels (i.e. 89Zr and Cy5.5) on [S]-HDL, [S]-PM, and [S]-LIP eluted at the same time on size-exclusion chromatography columns, indicative of proper label stability.

3.4. Pharmacokinetics, in vivo imaging and biodistribution

In vivo evaluation of the three [S]-nanomedicines started with an assessment of their circulation kinetics in Apoe−/− mice using gamma counting to quantify blood radioactivity levels over time (Fig. 3B). After 24 h, [S]-PM and [S]-LIP showed longer circulation times in blood in comparison with [S]-HDL (~10% ID/g remaining in blood vs ~1% ID/g for [S]-HDL). The longer circulation times for [S]-PM and [S]-LIP is likely related to their PEGylated surface and relatively large size as compared to [S]-HDL.

To study the tissue distribution of the [S]-nanomedicines non-invasively, we employed PET/CT imaging (Fig. 3C). PET imaging offers high sensitivity with deep tissue penetration [50,61]. At 24 h after injection, PET/CT imaging showed predominant accumulation in liver and spleen. This is in line with the dominant role of mononuclear phagocytotic system (MPS) macrophages in the removal of intravenously administered nanosystems [62]. [S]-HDL showed a relatively high signal in the kidneys, in line with a previously reported [50,63,64] renal clearance of comparatively smaller nanoparticles. The total body signal detected in mice which received [S]-PM or [S]-LIP was higher than that of [S]-HDL, implying faster body clearance of the latter (Supporting Fig. 5).

We subsequently excised the tissues of interest from Apoe−/− mice and analyzed their radioactivity content 24 h after i.v. administration. Ex vivo analysis of the radioactivity distribution corroborated the observations from pharmacokinetic and PET imaging studies (Fig. 3D and E). [S]-PM and [S]-LIP showed the highest accumulation in spleen and liver, ~25–30% ID/g and 10–15% ID/g, respectively (Fig. 3D), while [S]-HDL showed relatively high kidney accumulation. These results were in line with the qualitative autoradiographic analysis (Fig. 3E) and NIRF imaging (Supporting Fig. 6).

3.5. Targeting to atherosclerotic plaques and lesion-associated macrophages and monocytes

We investigated the plaque targeting ability of the [S]-

Table 1

|          | [S]-HDL | [S]-PM | [S]-LIP |
|----------|---------|--------|---------|
| Zaverage | 50 ± 6 nm | 80 ± 7 nm | 94 ± 10 nm |
| PDI      | 0.22 ± 0.03 | 0.11 ± 0.01 | 0.10 ± 0.06 |
| Zeta (ζ) potential (mV) | −15.8 ± 3.5 | −5.1 ± 0.9 | −15.1 ± 0.7 |
| EE (%)   | 60 ± 7% | 65 ± 8% | 71 ± 3% |

Data are presented as mean ± SD of three separately prepared batches of [S]-HDL, [S]-PM, or [S]-LIP. [S]: simvastatin; HDL: high density lipoprotein; PM: polymeric micelles; LIP: liposomes; Zave.: Z average; mV: millivolt; PDI: polydispersity index; EE: entrapment efficiency.
nanomedicines Apoe\(^{-/-}\) mice aortas. Interestingly, using gamma counting, the radioactivity concentrations in the excised aortas were similar for the three formulations (\(\sim 1.5-2\%\) ID/g) with no statistically significant differences (Fig. 3D, right). These findings are especially striking given the difference in blood circulation half-lives. We also evaluated regional distribution within the aorta using autoradiography and NIRF imaging for the three formulations (Fig. 4A). We found colocalization between radioactivity disposition and NIRF signal in the focal atherosclerotic lesions, especially in aortic roots, an area which is known to reproducibly develop atherosclerotic plaque [65–67].

Since macrophages and monocytes are the key immune cells that drive atherosclerosis progression [9], we sought to study the uptake of the three [S]-nanomedicine types by these key cells in aortic plaques of Apoe\(^{-/-}\) mice with advanced atherosclerosis. We applied a flow cytometry protocol and gating procedures adapted from previous studies [8,47] (Fig. 4B). After 24 h i.v. administration, the aortas were excised, and the uptake of Cy5.5 labeled-[S]-nanomedicines by macrophages and monocytes was quantified. Interestingly, distinct uptake patterns for the three [S]-nanomedicines by aortic macrophages and Ly6C\(^{\text{high}}\) monocytes were found (Fig. 4C and D). The HDL formulation showed relatively high uptake by aortic macrophages, in line with what was previously reported in atherosclerosis and cancer models [44,47]. Interestingly, [S]-PM showed a similar degree of high uptake, not only by aortic macrophages but also by Ly6C\(^{\text{high}}\) monocytes. On the other hand, [S]-LIP demonstrated the lowest macrophage/monocyte targeting efficiency in comparison to the other two formulations (Fig. 4C and D).

Although our efficacy readout parameter for [S]-nanomedicine treatment was reduction in aortic plaque macrophage/monocyte content, uptake by other immune cell types present in the blood pool and spleen may affect treatment outcome. Similar to our findings in the aorta, [S]-PM showed a much higher affinity for blood Ly6C\(^{\text{high}}\) monocytes in comparison to [S]-HDL and [S]-LIP (\(\sim 10\) fold and \(\sim 5\) fold, respectively, Supporting Fig. 7). Similarly, the association of [S]-PM with blood dendritic cells (DC) was also much higher than for [S]-HDL and [S]-LIP (\(\sim 29\) fold and 8 fold, respectively, Supporting Fig. 7). Also, in the spleen (Supporting Fig. 8), [S]-PM showed superior targeting efficiency towards the phagocytic target cells.

3.6. Therapeutic efficacy and safety

Reducing the number of plaque macrophages has been shown to decrease vessel wall inflammation and improve therapeutic outcomes in several key studies [8,10,39]. Also, blocking the recruitment of pro-inflammatory monocytes is a rational strategy to reduce inflammation in atherosclerotic plaques [68] and other diseases [69,70]. Here, we quantitatively assessed the efficacy of [S]-nanomedicine treatment by evaluating plaque macrophage/monocyte content using flow cytometry. Apoe\(^{-/-}\) mice with advanced atherosclerosis were administered three doses of [S]-HDL, [S]-PM, [S]-LIP (60 mg/Kg simvastatin per dose), equivalent oral simvastatin (as control), or PBS i.v. (as placebo) (Fig. 5A). All mice (\(n = 8-10\)/group) were age-matched and received the assigned treatments within a single week. Aortic macrophages and pro-inflammatory Ly6C\(^{\text{high}}\) monocytes were gated as described before in Fig. 4B. As compared to the controls saline and oral simvastatin, a significant decrease in plaque macrophage content was observed in the [S]-PM and [S]-HDL treatment groups (Fig. 5B). [S]-LIP and oral [S] treatment groups did not yield significant reductions in plaque macrophage content (vs. saline treatment). Interestingly, none of the
nanomedicine treatments had a statistically significant impact on plaque Ly6C<sup>high</sup> monocyte content, indicating that the different treatments did not affect monocyte recruitment, in line with what we observed previously [38,39].

We further analyzed blood as the direct recruitment pool for monocytes and other immune cells. None of the treatment groups showed a significant change in the number of total circulating leukocytes, monocytes, neutrophils, lymphocytes, red blood cells (RBCs), or platelets (vs. saline) (Fig. 5C). Additionally, the [S]-nanomedicine treatments did not significantly alter the concentration of serum triglycerides, total cholesterol, and glucose (vs. oral [S] treatment or placebo) (Supporting Fig. 9). Similarly, no significant concentration changes were found in toxicity blood markers (Supporting Fig. 9).

Nanomedicines are developed to ultimately achieve local, targeted drug delivery to pathological lesions (atherosclerotic plaques in our study) upon intravenous injection, aiming to improve the therapeutic efficacy and safety profile of the free drug. Nanocarrier characteristics such as composition, size, and morphology, which likely affect their circulation kinetics, drug release kinetics, extravasation, penetration, and importantly, specificity to the target cell(s), will have a direct impact on the therapeutic efficacy of nanomedicines. In our study, all treatments contained the same drug, the HMG-CoA reductase inhibitor simvastatin, which was administered at the same dose, and evaluated in age/diet matched Apoe<sup>−/−</sup> mice, a well-established model of atherosclerosis [71].

In our head-to-head study, we found the [S]-LIP yielded the least efficacy in reducing macrophage burden in atherosclerotic plaques. Although [S]-LIP possessed a long blood half-life, its poor plaque macrophage targeting efficiency, in addition to leakage of simvastatin from liposomes in circulation, might have contributed to this low efficacy. On the contrary, despite its comparatively shorter circulation half-life, [S]-HDL demonstrated better efficacy than [S]-LIP. This noticeable difference is probably due to HDL’s high specificity for plaque macrophages. These results also suggest that HDL can be an ideal imaging probe for lesion-associated macrophages [44,50]. Among the three platforms, [S]-PM demonstrated the most favorable features of a targeted drug delivery approach, including long circulation times, increased drug-nanocarrier stability in serum, and improved cellular targeting efficiency. These features resulted in the most prominent reduction in plaque macrophage burden. Remarkably, although the three nanomedicines showed uptake by pro-inflammatory Ly6C<sup>high</sup> monocytes, especially [S]-PM, none of the treatments altered monocyte content in atherosclerotic plaques. These different treatment effects on plaque macrophages and monocytes are in line with the new paradigm that considers atherosclerosis as a multiphasic process in which local macrophage proliferation, rather than monocyte recruitment, governs advanced atherosclerotic plaque progression [8,72]. Thus, tackling monocyte recruitment in advanced atherosclerosis with (nano-) medicines may not be an ideal approach for atheroprotection as demonstrated by Lindau et al. [73]. However, blocking the recruitment of pro-inflammatory monocytes may be imperative in conditions/diseases in which active monocytosis and recruitment can exacerbate the inflammatory response. An example of these conditions is the rapid inflammatory response triggered by acute myocardial infarction [68].

Additionally, the three [S]-nanomedicines did not change the metabolic parameters in plasma nor significantly alter major biomarkers of HMG-CoA reductase inhibitor-induced myo- or hepatotoxicity [37]. Moreover, HDL - one of our body’s own nanoparticles - and liposomes are well known for their biocompatibility and biodegradability. PM composed of pHPMA polymers are also known to be non-immunogenic.
and biocompatible [74–76]; they have been extensively investigated for drug delivery (reviewed by Talelli et al. [56]) Moreover, several pHMA-based therapies have been clinically evaluated (reviewed by Duncan and Vicent [77]). Our data indicate the safety of our treatments, an important step for the potential clinical translation of the nanomedicines under investigation. However, more detailed safety studies will need to be executed before any clinical application. Furthermore, factors such manufacturability under good manufacture practice (GMP) conditions, cost, patient selection, and best therapeutic approach (e.g. high dose short-term injections with and without oral therapy) also need to be carefully considered for clinical translation [78].

4. Conclusions

In this systematic head-to-head study, we have adopted sensitive, quantitative techniques to evaluate three clinically applicable nanomedicines targeting HMG-CoA reductase, in regards to their physicochemical characteristics and in vivo performance in ApoE−/− mice with advanced atherosclerosis. It was found that [S]-PM possesses superior efficacy, in comparison to [S]-HDL and [S]-LIP, to locally reduce the macrophage burden in advanced atherosclerotic plaques. This is likely due to the higher targeted drug delivery efficiency, as a result of the combination of the enhanced retention of simvastatin in the polymeric micelles and the high cellular targeting efficiency to plaque macrophages. These findings are crucial for further development and clinical application of nanomedicines to reduce inflammation in advanced atherosclerosis. Furthermore, the work presented in this paper suggests that the systematic investigation of nanomaterials, beyond cancer, is crucial for the future of nanomedicine design, optimization, and clinical applicability in several disease contexts.
