Component response rate variation underlies the stability of complex systems

A. Bradley Duthie

Biological and Environmental Sciences, University of Stirling, Stirling, UK, FK9 4LA
alexander.duthie@stir.ac.uk

The stability of a complex system generally decreases with increasing system size and interconnectivity, a counterintuitive result of widespread importance across the physical, life, and social sciences. Despite recent interest in the relationship between system properties and stability, the effect of variation in the response rate of individual system components remains unconsidered. Here I vary the component response rates ($\gamma$) of randomly generated complex systems. I show that when component response rates vary, the potential for system stability is markedly increased. Variation in $\gamma$ is especially important for stability in highly complex systems, in which the probability of stability would otherwise be negligible. At such extremes of simulated system complexity, the largest stable complex systems would be unstable if not for $\text{Var}(\gamma)$. My results therefore reveal a previously unconsidered aspect of system stability that is likely to be pervasive across all realistic complex systems.

In 1972, May\textsuperscript{1} first demonstrated that randomly assembled systems of sufficient complexity are almost inevitably unstable given infinitesimally small perturbations. Complexity in this case is defined by the size of the system (i.e., the number of potentially interacting components; $S$), its connectance (i.e., the probability that one component will interact with another; $C$), and the variance of interaction strengths ($\sigma^2$). May’s finding that the probability of local stability falls to near zero given a sufficiently high threshold of $\sigma\sqrt{SC}$ is broadly relevant for understanding the dynamics and persistence of systems such as ecological\textsuperscript{1–5}, neurological\textsuperscript{6,7}, biochemical\textsuperscript{8,9}, and socio-economic\textsuperscript{10–13} networks. As such, identifying general principles that affect stability in complex systems is of wide-ranging importance.

Randomly assembled complex systems can be represented as large square matrices ($M$) with $S$ components (e.g., networks of species\textsuperscript{2} or banks\textsuperscript{11}). One element of such a matrix, $M_{ij}$, defines how component $j$ affects component $i$ in the system at a point of equilibrium\textsuperscript{2}. Off-diagonal elements ($i \neq j$) therefore define interactions between components, while diagonal elements ($i = j$) define component self-regulation (e.g., carrying capacity in ecological communities). Traditionally, off-diagonal elements are assigned non-zero values with a probability $C$, which are sampled from a distribution with variance $\sigma^2$; diagonal elements are set to $-1$.\textsuperscript{1,2,4} Local system stability is assessed using eigenanalysis, with the system being stable if the real parts of all eigenvalues ($\lambda$) of $M$ are negative ($\max(\Re(\lambda)) < 0$). In a large system (high $S$), eigenvalues are distributed uniformly\textsuperscript{14} within a circle centred at $\Re = -1$ (the mean value of diagonal elements) and $\Im = 0$, with a radius of $\sigma\sqrt{SC}$\textsuperscript{1,2,4} (Figs 1a and 2a). Local stability of randomly assembled systems therefore becomes increasingly unlikely as $S$, $C$, and $\sigma^2$ increase.

May’s\textsuperscript{1,2} stability criterion $\sigma\sqrt{SC} < 1$ assumes that the expected response rates ($\gamma$) of individual components to perturbations of the system are identical, but this is highly unlikely in any complex system. In ecological communities, for example, the rate at which population density changes following perturbation will depend on the generation time of organisms, which might vary by orders of magnitude among species. Species with short generation times will respond quickly (high $\gamma$) to perturbations relative to species with long generation times (low $\gamma$). Similarly, the speed at which individual banks respond to perturbations in financial networks, or individuals or institutions respond to perturbations in complex social networks, is likely to vary. The effect of such variance on stability has not been investigated in complex systems theory. Intuitively, variation in $\gamma$ might be expected to decrease system stability by introducing a new source of variation into the system and thereby increasing $\sigma$. Here I show why, despite higher $\sigma$, realistic complex systems (such that $S$ is high but finite) are actually more likely to be stable if their individual component response rates vary.
Results

Component response rates of random complex systems. Rows in $M$ define how a given component $i$ is affected by other components of the system, meaning that the rate of component response time can be modelled by multiplying all row elements by a real scalar value $\gamma_i$. The distribution of $\gamma$ over $S$ components thereby models the distribution of component response rates. An instructive example compares one $M$ where $\gamma_i = 1$ for all $i$ in $S$ to the same $M$ when half of $\gamma_i$ = 1.95 and half of $\gamma_i = 0.05$. This models one system in which $\gamma$ is invariant and one in which $\gamma$ varies, but systems are otherwise identical (note that mean $\gamma_i = 1$ in both cases). I assume $S = 200$, $C = 0.05$, and $\sigma = 0.4$; diagonal elements are set to $-1$ and non-zero off-diagonal elements are drawn randomly from $\mathcal{N}(0, \sigma^2)$. Rows are then multiplied by $\gamma_i$ to generate $M$. When $\gamma_i = 1$, eigenvalues of $M$ are distributed uniformly within a circle centred at $(-1,0)$ with a radius of 1.265 (Fig. 1a). Hence, the real components of eigenvalues are highly unlikely to all be negative when all $\gamma_i = 1$. But when $\gamma_i$ values are separated into two groups, eigenvalues are no longer uniformly distributed (Fig. 1b). Instead, two distinct clusters of eigenvalues appear (red circles in Fig. 1b), one centred at $(\lambda, \mu)$ and the other centred at $(-0.05,0)$. The former has a large radius, but the real components have shifted to the left (in comparison to when $\gamma = 1$), while the latter cluster has a smaller radius, but real components have shifted to the right; all $\mathbb{R}(\lambda) < 0$. Overall, for 1 million randomly assembled $M$, this division between slow and fast component response rates results in more stable systems: 1 stable given $\gamma = 1$ versus 32 stable given $\gamma = \{1.95, 0.5\}$.

Higher stability in systems with variation in $\gamma$ can be observed by sampling $\gamma_i$ values from various distributions. I focus on a uniform distribution where $\gamma \sim \mathcal{U}(0,2)$ (see Supplementary Information for other distributions, which give similar results). As with the case of $\gamma = \{1.95, 0.5\}$ (Fig. 1b), mean $\gamma = 1$ when $\gamma \sim \mathcal{U}(0,2)$, allowing comparison of $M$ before and after the addition of variation in component response rate. Figure 2 shows a comparison of eigenvalue distributions given $S = 1000$, $C = 0.05$, and $\sigma = 0.4$. As expected, when $\gamma = 1$, eigenvalues are distributed uniformly in a circle centred at $(-1,0)$ with a radius of $\sigma \sqrt{SC} = 2.828$. Uniform variation in $\gamma$ leads to a non-uniform distribution of eigenvalues, some of which are clustered locally near the centre of the distribution, but others of which are spread outside the former radius of 2.828 (Fig 2b). The clustering and spreading of eigenvalues introduced by $Var(\gamma)$ can destabilise previously stable systems or stabilise systems that are otherwise unstable. But where systems are otherwise too complex to be stable given $\gamma = 1$, the effect of $Var(\gamma)$ can often lead to stability above May’s threshold $\sigma \sqrt{SC} < 1$.

Simulation of random M across S. To investigate the effect of $Var(\gamma)$ on stability across systems of varying complexity, I simulated random $M$ matrices at $\sigma = 0.4$ and $C = 1$ across $S = \{2, 3, ..., 49, 50\}$. One million $M$ were simulated for each $S$, and the stability of $M$ was assessed given $\gamma = 1$ versus $\gamma \sim \mathcal{U}(0,2)$. For all $S > 10$, I found that the number of stable random systems was higher given $Var(\gamma)$ than when $\gamma = 1$ (Fig. 3; see Supplementary Information for full table of results), and that the difference between the probabilities of observing a stable system increased with an increase in $S$. In other words, the potential for $Var(\gamma)$ to affect stability increased with system complexity and was most relevant for systems on the cusp of being too complex to be realistically stable. For the highest values of $S$, nearly all systems that were stable given $Var(\gamma)$ would not have been stable given $\gamma = 1$.

Targeted manipulation of $\gamma$. To further investigate the potential of $Var(\gamma)$ to be stabilising, I used a genetic algorithm. Genetic algorithms are heuristic tools that mimic evolution by natural selection, and are useful when the space of potential solutions (in this case, possible combinations of $\gamma$ values leading to stability in a complex system) is too large to search exhaustively. Generations of selection on $\gamma$ value combinations to minimise max $(\mathbb{R}(\lambda))$ demonstrated the potential for $Var(\gamma)$ to increase system stability. Across $S = \{2, 3, ..., 39, 40\}$, sets of $\gamma$ values were found that resulted in stable systems with probabilities that were up to four orders of magnitude higher than when $\gamma = 1$ (Fig. 4), meaning that stability could often be achieved by manipulating $S$ $\gamma$ values rather than $S \times S$ $M$ elements (i.e., by manipulating component response rates rather than interactions between components).

System feasibility given $Var(\gamma)$. For complex systems in which individual system components represent the density of some tangible quantity, it is relevant to consider the feasibility of the system. Feasibility assumes that values of all components are positive at equilibrium. This is of particular interest for ecological communities because population density ($N$) cannot take negative values, meaning that ecological
systems need to be feasible for stability to be biologically realistic\textsuperscript{20}. While my results are intended to be general to all complex systems, and not restricted to species networks, I have also performed a feasibility analysis on all matrices $M$ tested for stability, and additionally for specific types of ecological communities\textsuperscript{2} (e.g., competitive, mutualist, predator-prey; see Supplementary Information). I emphasise that $\gamma$ is not interpreted as population density in this analysis, but instead as a fundamental property of species life history such as expected generation time. Feasibility was unaffected by $\text{Var}(\gamma)$ and instead occurred with a fixed probability of $1/2^2$, consistent with a recent proof by Serván et al.\textsuperscript{22} (see Supplementary Information). Hence, for pure interacting species networks, variation in component response rate (i.e., species generation time) does not affect stability at biologically realistic species densities.

Figure 1: Example distribution of eigenvalues before (a) and after (b) separating a randomly generated complex system into fast ($\gamma = 1.95$) and slow ($\gamma = 0.05$) component response rates. Each panel shows the same system where $S = 200$, $C = 0.05$, and $\sigma = 0.4$, and in each case $E[\gamma] = 1$ (i.e., only the distribution of $\gamma$ differs between panels). a. Eigenvalues plotted when all $\gamma = 1$; distributions of points are uniformly distributed within the blue circle with a radius of $\sigma \sqrt{SC} = 1.238$ centred at -1 on the real axis. b. Eigenvalues plotted when half $\gamma = 1.95$ and half $\gamma = 0.05$; distributions of points can be partitioned into one large circle centred at $\gamma = -1.95$ and one small circle centred at $\gamma = -0.05$. In a, the maximum real eigenvalue $\max(\Re(\lambda)) = 0.2344871$, while in b $\max(\Re(\lambda)) = -0.000273135$, meaning that the complex system in b but not a is stable because $\max(\Re(\lambda)) < 0$. In 1 million randomly generated complex systems under the same parameter values, 1 was stable when $\gamma = 1$ while 32 were stable when $\gamma = \{1.95, 0.05\}$. Overall, complex systems that are separated into fast versus slow components tend to be more stable than otherwise identical systems with identical component response rates.
**Discussion**

I have shown that the stability of complex systems might often be contingent upon variation in the response rates of their individual components, meaning that factors such as rate of trait evolution (in biological networks), transaction speed (in economic networks), or communication speed (in social networks) need to be considered when investigating the stability of complex systems. Variation in component response rate is more likely to be critical for stability in systems that are especially complex, and it can ultimately increase the probability that system stability is observed above that predicted by May’s classically derived $\sigma \sqrt{SC}$ criterion. The logic outlined here is general, and potentially applies to any complex system in which individual system components can vary in their reaction rates to system perturbation.

**Figure 2: Distributions of eigenvalues before (a) and after (b) introducing variation in component response rate ($\gamma$) in complex systems.** Each panel show the same system where $S = 1000$, $C = 0.05$, and $\sigma = 0.4$. **a.** Eigenvalues plotted in the absence of $\text{Var}(\gamma)$ where $E[\gamma] = 1$, versus **b.** eigenvalues plotted given $\gamma \sim \mathcal{U}(0, 2)$, which increases the variance of interaction strengths ($\sigma^2$) but also creates a cluster of eigenvalues toward the distribution’s centre (-1, 0). Blue ellipses in both panels show the circle centred on the distribution in panel a. Proportions of $\Re(\lambda) < 0$ are 0.724 and 0.742 for a and b, respectively.

It is important to recognise that variation in component response rate is not stabilising per se; that is, adding variation in component response rates to a particular system does not increase the probability that the system will be stable. Rather, highly complex systems that are observed to be stable are more likely to have varying component response rates, and for this variation to be critical to their stability (Fig. 3). This is caused by the shift to a non-uniform distribution of eigenvalues that occurs by introducing $\text{Var}(\gamma)$ (Fig. 1b, 2b), which can sometimes cause all of the real components of the eigenvalues of the system matrix to become negative, but might also increase the real components of eigenvalues.
Figure 3: Stability of large complex systems with and without variation in component response rate (γ). The ln number of systems that are stable across different system sizes (S, max S = 50) given C = 1, and the proportion of systems in which variation in γ is critical for system stability. For each S, 1 million complex systems are randomly generated. Stability of each complex system is tested given variation in γ by randomly sampling γ ∼ 𝑈(0, 2). Stability given Var(γ) is then compared to stability in an otherwise identical system in which γ = E[𝑈(0, 2)] for all components. Blue and red bars show the number of stable systems in the absence and presence of Var(γ), respectively. The black line shows the proportion of systems that are stable when Var(γ) > 0, but would be unstable if Var(γ) = 0.

My focus is distinct from Gibbs et al.\textsuperscript{17}, who applied the same mathematical framework to investigate how a diagonal matrix X (equivalent to γ in my model) affects the stability of a community matrix M given an interaction matrix A within a generalised Lotka-Volterra model, where M = XA. Gibbs et al.\textsuperscript{17} analytically demonstrated that the effect of X on system stability decreases exponentially as system size becomes arbitrarily large (S → ∞) for a given magnitude of complexity \( \sigma \sqrt{SC} \). My numerical results do not contradict this prediction because I did not scale \( \sigma = 1/\sqrt{S} \), but instead fixed \( \sigma \) and increased S to thereby increase total system complexity (see Supplementary Information for results simulated across \( \sigma \) and C). Overall, I show that component response rate variation increases the upper bound of complexity at which stability can be realistically observed, meaning that highly complex systems are more likely than not to vary in their component response rates, and for this variation to be critical for system stability.

The potential importance of component response rate variation was most evident from the results of simulations in which the genetic algorithm was used in attempt to maximise the probability of system stability. The
probability that some combination of component response rates could be found to stabilise the system was shown to be up to four orders of magnitude higher than the background probabilities of stability in the absence of any component response rate variation. Instead of manipulating the $S \times S$ interactions between system components, it might therefore be possible to manipulate only the $S$ response rates of individual system components to achieve stability. Hence, managing the response rates of system components in a targeted way could potentially facilitate the stabilisation of complex systems through a reduction in dimensionality.

**Figure 4: Stability of large complex systems given $\gamma = 1$ versus targeted $\text{Var}(\gamma)$**. The ln number of systems that are stable across different system sizes ($S$, max $S = 40$) for $C = 1$, and the proportion of systems wherein a targeted search of $\gamma$ values successfully resulted in system stability. For each $S$, 100000 complex systems are randomly generated. Stability of each complex system is tested given variation in $\gamma$ using a genetic algorithm to maximise the effect of $\gamma$ values on increasing stability, as compared to stability in an otherwise identical system in which $\gamma$ is the same for all components. Blue bars show the number of stable systems in the absence of component response rate variation, while red bars show the number of stable systems that can be generated if component response rate is varied to maximise system stability. The black line shows the proportion of systems that are stable when component response rate is targeted to increase stability, but would not be stable if $\text{Var}(\gamma) = 0$.

Interestingly, while complex systems were more likely to be stable given variation in component response rate, they were not more likely to be feasible, meaning that stability was not increased when component values were also restricted to being positive at equilibrium. Feasibility is important to consider, particularly for the study of ecological networks of species\textsuperscript{5,18,20,22} because population densities cannot realistically be negative.
My results therefore suggest that variation in the rate of population responses to perturbation (e.g., due to differences in generation time among species) is unlikely to be critical to the stability of purely multi-species interaction networks (see also Supplementary Information). Nevertheless, ecological interactions do not exist in isolation in empirical systems, but instead interact with evolutionary, abiotic, or social-economic systems. The relevance of component response rate for complex system stability should therefore not be ignored in the broader context of ecological communities.

A general mathematical framework encompassing shifts in eigenvalue distributions caused by a vector $\gamma$ has been investigated\(^{16}\) and recently applied to questions concerning species density and feasibility\(^{17,18}\), but $\gamma$ has not been interpreted as rates of response of individual system components to perturbation. My model focuses on component response rates for systems of a finite size, in which complexity is high but not yet high enough to make the probability of stability unrealistically low for actual empirical systems. For this upper range of system size, randomly assembled complex systems are more likely to be stable if their component response rates vary (e.g., $10 < S < 30$ for parameter values in Fig. 3). Overall, I suggest that variation in component response rate might therefore be critical for maintaining stability in many highly complex empirical systems. These results are broadly applicable for understanding the stability of complex networks across the physical, life, and social sciences.

Methods

**Component response rate variation ($\gamma$).** In a synthesis of eco-evolutionary feedbacks on community stability, Patel et al. model a system that includes a vector of potentially changing species densities ($N$) and a vector of potentially evolving traits ($x$)\(^{15}\). For any species $i$ or trait $j$, change in species density ($N_i$) or trait value ($x_j$) with time ($t$) is a function of the vectors $N$ and $x$,

$$\frac{dN_i}{dt} = N_i f_i(N, x),$$

$$\frac{dx_j}{dt} = \epsilon g_j(N, x).$$

In the above, $f_i$ and $g_j$ are functions that define the effects of all species densities and trait values on the density of a species $i$ and the value of trait $j$, respectively. Patel et al. were interested in stability when the evolution of traits was relatively slow or fast in comparison with the change in species densities\(^{15}\), and this is modulated in the above by the scalar $\epsilon$. The value of $\epsilon$ thereby determines the timescale separation between ecology and evolution, with high $\epsilon$ modelling relatively fast evolution and low $\epsilon$ modelling relatively slow evolution\(^{15}\).

I use the same principle that Patel et al. use to modulate the relative rate of evolution to modulate rates of component responses for $S$ components. Following May\(^{1,23}\), the value of a component $i$ at time $t$ ($v_i(t)$) is affected by the value of $j$ ($v_j(t)$) and $j$‘s marginal effect on $i$ ($a_{ij}$), and by $i$‘s response rate ($\gamma_i$),

$$\frac{dv_i(t)}{dt} = \gamma_i \sum_{j=1}^{S} a_{ij} v_j(t).$$

In matrix notation\(^{23}\),

$$\frac{dv(t)}{dt} = \gamma A v(t).$$

In the above, $\gamma$ is a diagonal matrix in which elements correspond to individual component response rates. Therefore, $M = \gamma A$ defines the values of system components and can be analysed using the techniques of May\(^{1,16,23}\). In these analyses, row means of $A$ are expected to be identical, but variation around this
expectation will naturally arise due to random sampling of $A$ off-diagonal elements and finite $S$. In simulations, the total variation in $M$ row means that is attributable to $A$ is small relative to that attributable to $γ$, especially at high $S$. Variation in $γ$ specifically isolates the effects of differing component response rates, hence causing differences in expected $M$ row means.

**Genetic algorithm.** Ideally, to investigate the potential of $Var(γ)$ for increasing the proportion of stable complex systems, the search space of all possible $γ$ vectors would be evaluated for each unique $M = γA$. This is technically impossible because $γ_i$ can take any real value between 0-2, but even rounding $γ_i$ to reasonable values would result in a search space too large to practically explore. Under these conditions, genetic algorithms are highly useful tools for finding practical solutions by mimicking the process of biological evolution\textsuperscript{19}. In this case, the practical solution is finding vectors of $γ$ that decrease the most positive real eigenvalue of $M$. The genetic algorithm used achieves this by initialising a large population of 1000 different potential $γ$ vectors and allowing this population to evolve through a process of mutation, crossover (swapping $γ_i$ values between vectors), selection, and reproduction until either a $γ$ vector is found where all $ℜ(λ) < 0$ or some “giving up” criteria is met.

For each $S = \{2, 3, ..., 39, 40\}$, the genetic algorithm was run for 100000 random $M$ ($σ = 0.4, C = 1$). The genetic algorithm was initialised with a population of 1000 different $γ$ vectors with elements sampled i.i.d from $γ_i \sim U(0, 2)$. Eigenanalysis was performed on the $M$ resulting from each $γ$ vector, and the 20 $γ$ vectors resulting in $M$ with the lowest max ($ℜ(λ)$) each produced 50 clonal offspring with subsequent random mutation and crossover between the resulting new generation of 1000 $γ$ vectors. Mutation of each $γ_i$ in a $γ$ vector occurred with a probability of 0.2, resulting in a mutation effect of size $N(0, 0.02)$ being added to generate the newly mutated $γ_i$ (any $γ_i$ values that mutated below zero were multiplied by $−1$, and any values that mutated above 2 were set to 2). Crossover occurred between two sets of 100 $γ$ vectors paired in each generation; vectors were randomly sampled with replacement among but not within sets. Vector pairs selected for crossover swapped all elements between and including two $γ_i$ randomly selected with replacement (this allowed for reversal of vector element positions during crossover; e.g., $\{γ_4, γ_5, γ_6, γ_7\} \rightarrow \{γ_7, γ_6, γ_5, γ_4\}$). The genetic algorithm terminated if a stable $M$ was found, 20 generations occurred, or if the mean $γ$ fitness increase between generations was less than 0.01 (where fitness was defined as $W_γ = −\max ℜ(λ)$ for $M$).

**System feasibility.** Dougoud et al.$\textsuperscript{20}$ identify the following feasibility criteria for ecological systems characterised by $S$ interacting species with varying densities in a generalised Lotka-Volterra model,

$$n^* = −(θI + (CS)^{−δ}J)^{−1}r.$$  

In the above, $n^*$ is the vector of species densities at equilibrium. Feasibility is satisfied if all elements in $n^*$ are positive. The matrix $I$ is the identity matrix, and the value $θ$ is the strength of intraspecific competition (diagonal elements). Diagonal values are set to $−1$, so $θ = −1$. The variable $δ$ is a normalisation parameter that modulates the strength of interactions ($σ$) for $J$. Implicitly, here $δ = 0$ underlying strong interactions. Hence, $(CS)^{−δ} = 1$, so in the above, a diagonal matrix of -1s ($θI$) is added to $J$, which has a diagonal of all zeros and an off-diagonal affecting species interactions (i.e., the expression $(CS)^{−δ}$ relates to May’s\textsuperscript{31} stability criterion by $\frac{CS^{−δ}}{\sqrt{SC}} < 1$, and hence for my purposes $(CS)^{−δ} = 1$). Given $A = θI + J$, the above criteria is therefore reduced to the below\textsuperscript{22},

$$n^* = −A^{−1}r.$$  

To check the feasibility criteria for $M = γA$, I therefore evaluated $−M^{−1}r$ ($r$ elements were sampled i.i.d. from $r_i \sim N(0, 0.4^2)$). Feasibility is satisfied if all of the elements of the resulting vector are positive.

Stability across increasing $S$

Figure 3 of the main text reports the number of stable random complex systems found over 1 million iterations. The table below shows the results for all simulations of random $M$ matrices at $\sigma = 0.4$ and $C = 1$ given a range of $S = \{2, 3, \ldots, 49, 50\}$. In this table, the $A_0$ refers to matrices where $\gamma = 1$, while $A_1$ refers to matrices after $Var(\gamma)$ is added and $\gamma \sim U(0, 2)$. Each row summarises data for a given $S$ over 1 million randomly simulated $M$ ($A_0$ and $A_1$). The column $A_0\_unstable$ shows the number of $A_0$ matrices that are unstable, and the column $A_0\_stable$ shows the number of $A_0$ matrices that are stable (these two columns sum to 1 million). Similarly, the column $A_1\_unstable$ shows the number of $A_1$ matrices that are unstable and $A_1\_stable$ shows the number that are stable. The columns $A_1\_stabilised$ and $A_1\_destabilised$ show how many $A_0$ matrices were stabilised or destabilised, respectively, by $Var(\gamma)$.
| S  | A0_unstable | A0_stable   | A1_unstable | A1_stable | A1_stabilised | A1_destabilised |

Overall, the ratio of stable A1 matrices to stable A0 matrices found is greater than 1 whenever $S > 10$ (compare column 5 to column 3), and this ratio increases with increasing $S$ (column 1). Hence, more randomly
created complex systems ($M$) are stable given variation in $\gamma$ than when $\gamma = 1$. Note that feasibility results were omitted for the table above, but are reported below.

Stability given targeted manipulation of $\gamma$ (genetic algorithm)

Figure 4 of the main text reports the number of stable random complex systems found over 100000 using the genetic algorithm to maximise stability with a vector $\gamma$. Stability results for 100000 $M$ for each $S$ from 2-40 are shown below. Results for $A0$ indicate systems in which $\gamma = 1$, while $A1$ refers to systems in which the genetic algorithm searched for a set of $\gamma$ values that stabilised the system.

| S  | A0_unstable | A0_stable | A1_unstable | A1_stable | A1_stabilised | A1_destabilised |
|----|-------------|-----------|-------------|-----------|---------------|-----------------|

The distributions of nine $\gamma$ vectors from the highest $S$ values are shown below. This comparison shows the high number of stable $M$ that can be produced through a targeted search of $\gamma$ values, and suggests that many otherwise unstable systems could potentially be stabilised by an informed manipulation of their component response times. Such a possibility might conceivably reduce the dimensionality of problems involving stability in social-ecological or economic systems.

Distributions of $\gamma$ values in vectors for the highest values of $S$ are shown below.

The distribution of $\gamma$ values found by the genetic algorithm is uniform. A uniform distribution was used to initialise $\gamma$ values, so there is therefore no evidence that a particular distribution of $\gamma$ is likely to be found to stabilise a matrix $M$.

**Stability of ecological networks**

While the foundational work of May\(^1\) applies broadly to complex networks, much attention has been given specifically to ecological networks of interacting species. In these networks, the matrix $A$ is interpreted as a community matrix and each row and column is interpreted as a single species. The per capita effect that the density of any species $i$ has on the population dynamics of species $j$ is found in $A_{ij}$, meaning that $A$ holds the effects of pair-wise interactions between $S$ species\(^2,3\). While May’s original work\(^1\) considered only randomly assembled communities, recent work has specifically looked at more restricted ecological communities including competitive networks (all off-diagonal elements of $A$ are negative), mutualist networks (all off-diagonal elements of $A$ are positive), and predator-prey networks (for any pair of $i$ and $j$, the effect of $i$ on $j$ is negative and $j$ on $i$ is positive, or vice versa)\(^2,3\). In general, competitor and mutualist networks tend to be unstable, while predator-prey networks tend to be highly stabilising\(^2\).

I investigated competitor, mutualist, and predator-prey networks following Allesina et al.\(^2\). To create these networks, I first generated a random matrix $A$, then changed the elements of $A$ accordingly. If $A$ was a competitive network, then the sign of any positive off-diagonal elements was reversed to be negative. If $A$ was a mutualist network, then the sign of any positive off-diagonal elements was reversed to be positive. And if $A$ was a predator-prey network, then all $i$ and $j$ pairs of elements were checked; any pairs of the same sign were changed so that one was negative and the other was positive.
The number of stable $M = \gamma A$ systems was estimated exactly as it was in the main text for random matrices for values of $S$ from 2 to 50 (100 in the case of the relatively more stable predator-prey interactions), except that only 100000 random $M$ were generated instead of 1 million.

The following tables for restricted ecological communities can therefore be compared with the random $M$ results above (but note that counts from systems with comparable probabilities of stability will be an order of magnitude lower in the tables below due to the smaller number of $M$ matrices generated). As with the results above, in the tables below, $A_0$ refers to matrices when $\gamma = 1$ and $A_1$ refers to matrices after $\text{Var}(\gamma)$ is added. The column $A_0\text{ unstable}$ shows the number of $A_0$ matrices that are unstable, and the column $A_0\text{ stable}$ shows the number of $A_0$ matrices that are stable (these two columns sum to 100000). Similarly, the column $A_1\text{ unstable}$ shows the number of $A_1$ matrices that are unstable and $A_1\text{ stable}$ shows the number that are stable. The columns $A_1\text{ stabilised}$ and $A_1\text{ destabilised}$ show how many $A_0$ matrices were stabilised or destabilised, respectively, by $\text{Var}(\gamma)$.

## Competition

Results for competitor interaction networks are shown below

| N  | $A_0\text{ unstable}$ | $A_0\text{ stable}$ | $A_1\text{ unstable}$ | $A_1\text{ stable}$ | $A_1\text{ stabilised}$ | $A_1\text{ destabilised}$ |

Overall, as expected[^2], predator-prey communities are relatively stable while mutualist communities are highly unstable. But interestingly, while $Var(\gamma)$ stabilises predator-prey and competitor communities, it does not stabilise mutualist communities. This is unsurprising because purely mutualist communities are characterised by a very positive[^2] leading $ℜ(λ)$, and it is highly unlikely that $Var(\gamma)$ alone will shift all real parts of eigenvalues to negative values.

Sensitivity of connectance ($C$) values

In the main text, for simplicity, I assumed connectance values of $C = 1$, meaning that all off-diagonal elements of a matrix $M$ were potentially nonzero and sampled from a normal distribution $N(0, σ^2)$ where $σ = 0.4$. Here I present four tables showing the number of stable communities given $C = \{0.3, 0.5, 0.7, 0.9\}$. In all cases, uniform variation in component response rate ($γ ∼ U(0, 2)$) led to a higher number of stable communities than when $γ$ did not vary ($γ = 1$). In contrast to the main text, 100000 rather than 1 million $M$ were simulated. As with the results on stability with increasing $S$ shown above, in the tables below $A₀$ refers to matrices when $γ = 1$, and $A₁$ refers to matrices after $Var(\gamma)$ is added. The column $A₀\_unstable$ shows the number of $A₀$ matrices that are unstable, and the column $A₀\_stable$ shows the number that are stable (these two columns sum to 100000). Similarly, the column $A₁\_unstable$ shows the number of $A₁$ matrices that are unstable and $A₁\_stable$ shows the number that are stable. The columns $A₁\_stabilised$ and $A₁\_destabilised$ show how many $A₀$ matrices were stabilised or destabilised, respectively, by $Var(\gamma)$.

**Connectance $C = 0.3$**

| N  | A₀\_unstable | A₀\_stable | A₁\_unstable | A₁\_stable | A₁\_stabilised | A₁\_destabilised | A₀\_infeasible |

21
Sensitivity of interaction strength (\(\sigma\)) values

Results below show stability results given varying interaction strengths (\(\sigma\)) for \(C = 0.05\) (note that system size \(S\) values are larger and increase by 10 with increasing rows). In the tables below (as above), \(A0\) and \(A1\) refers to matrices for \(\gamma = 1\) and \(Var(\gamma)\), respectively.

### Interaction strength \(\sigma = 0.3\)

Sensitivity of distribution of $\gamma$

In the main text, I considered a uniform distribution of component response rates $\gamma \sim U(0, 2)$. The number of unstable and stable $M$ matrices are reported in a table above across different values of $S$. Here I show complementary results for three different distributions including an exponential, beta, and gamma distribution of $\gamma$ values. The shape of these distributions is shown in the figure below.

**Distributions of component response rate ($\gamma$) values in complex systems.** The stabilities of simulated complex systems with these $\gamma$ distributions are compared to otherwise identical complex systems with a fixed component response rate of $\gamma = 1$ across different system sizes ($S$; i.e., component numbers) given a unit $\gamma$ standard deviation ($\sigma_\gamma = 1$) for b-d. Distributions are as follows: (a) uniform, (b) exponential, (c) beta ($\alpha = 0.5$ and $\beta = 0.5$), and (d) gamma ($k = 2$ and $\theta = 2$). Each panel shows 1 million randomly generated $\gamma$ values.
The same 100000 $\mathbf{M}$ matrices were used to investigate stability when applying each of these different distributions of $\gamma$ values. The table below shows the number of $\mathbf{M}$ that were unstable (_unst) and stable (_stbl) for the exponential (Exp), beta, and gamma distributions.

| $S$ | Exp_unst | Exp_stbl | beta_unst | beta_stbl | gamma_unst | gamma_stbl |

In comparison to the uniform distribution (a), proportionally fewer random systems are found with the exponential distribution (b), while more are found with the beta (c) and gamma (d) distributions.

**Feasibility of complex systems**

When feasibility was evaluated with and without variation in $\gamma$, there was no increase in stability for $M$ where $\gamma$ varied as compared to where $\gamma = 1$. Results below illustrate this result, which was general to all other simulations performed.
| S  | A0_infeasible | A0_feasible | A1_infeasible | A1_feasible | A1_made_feasible | A1_made_infeasible |
|----|--------------|-------------|---------------|------------|------------------|-------------------|

| 46 | 1000000      | 0           | 1000000       | 0          | 0                | 0                 |
| 47 | 1000000      | 0           | 1000000       | 0          | 0                | 0                 |
| 48 | 1000000      | 0           | 1000000       | 0          | 0                | 0                 |
| 49 | 1000000      | 0           | 1000000       | 0          | 0                | 0                 |
| 50 | 1000000      | 0           | 1000000       | 0          | 0                | 0                 |

Hence, in general, $\text{Var}(\gamma)$ does not appear to affect feasibility in pure species interaction networks.

**Consistency with Gibbs et al. (2018)**

The question that I address in the main text is distinct from that of Gibbs et al.\textsuperscript{5}, who focused instead on the effect of a diagonal matrix of biological species densities $\mathbf{X}$ on a community matrix $\mathbf{M}$ given a species interaction matrix $\mathbf{A}$. This is modelled as below,

$$\mathbf{M} = \mathbf{X}\mathbf{A}.$$  

Mathematically, the above is identical to my model in the main text where the system $\mathbf{M}$ is defined by component interaction strengths $\mathbf{A}$ and individual component response rates $\gamma$, 

\textsuperscript{4}
\[ M = \gamma A. \]

I focused on the probability of observing a stable versus unstable system given variation in \( \gamma \) as system complexity \( (\sigma \sqrt{SC}) \) increased. I increased system complexity by holding \( C \) and \( \sigma \) constant and incrementally increasing \( S \) to obtain numerical results. In contrast, Gibbs et al.\(^5\) applied analytical techniques to instead focus on a different question concerning the effect of \( \gamma \) on the stability of \( M \) given \( A \) as \( S \to \infty \), with \( \sigma \) scaled so that \( \sigma = 1/\sqrt{S} \). Under such scaling, Gibbs et al.\(^5\) showed that the effect of \( \gamma \) on stability should decrease exponentially as \( S \) increases, which I demonstrate below by running simulations in which \( \sigma = 1/\sqrt{S} \).

Above table results can be compared to those of the main results. Note that 100000 (not 1 million), simulations are run to confirm consistency with Gibbs et al.\(^5\). The difference between my model and Gibbs et al.\(^5\) is that in the latter, $\sigma \sqrt{SC} = 1$ remains constant with increasing $S$. In the former, $\sigma \sqrt{SC}$ increases with $S$, so the expected complexity of the system also increases accordingly. Consequently, for the scaled $\sigma$ in the table above, systems are not more likely to be stabilised by $\gamma$ as $S$ increases, consistent with Gibbs et al.\(^5\). Note that overall stability does decrease with increasing $S$ due to the increased density of eigenvalues (see below).

![Graph](graph.png)

Complexity as a function of $S$ in the main text (solid) versus in Gibbs et al.\(^5\) (dashed).

When the complexity is scaled to $\sigma \sqrt{SC} = 1$, an increase in $S$ increases the eigenvalue density within a circle with a unit radius centred at $(-1, 0)$ on the complex plane. As $S \to \infty$, this circle becomes increasingly saturated. Gibbs et al.\(^5\) showed that a diagonal matrix $\gamma$ will have an exponentially decreasing effect on stability with increasing $S$. Increasing $S$ is visualised below, first with a system size $S = 100$.  

29
The left panel above shows the distribution of eigenvalues; the blue ellipse shows the unit radius within which eigenvalues are expected to be contained. The right panel shows how eigenvalue distributions change given $\gamma \sim U(0, 2)$. The vertical dotted line shows the threshold of stability, $\Re = 0$. Increasing to $S = 200$, the scaling $\sigma = 1/\sqrt{S}$ maintains the expected distribution of eigenvalues but increases eigenvalue density.

We can increase the system size to $S = 500$ and see the corresponding increase in eigenvalue density.
Finally, below shows an increase in system size to $S = 1000$.

In contrast, in the model of the main text, the complexity of the system is not scaled to $\sigma\sqrt{SC} = 1$. Rather, the density of eigenvalues within a circle centred at $(-1, 0)$ with a radius $\sigma\sqrt{SC}$ is held constant such that there are $S/\pi(\sigma\sqrt{SC})^2$ eigenvalues per unit area of the circle. As $S$ increases, so does the expected complexity of the system, but the density of eigenvalues remains finite causing error around this expectation. Below shows a system where $S = 100$, $C = 0.0625$, and $\sigma = 0.4$, where $\sigma\sqrt{SC} = 1$ (identical to the first example distribution above in which $S = 100$ and $\sigma = 1/\sqrt{S}$).
Now when $S$ is increased to 200 while keeping $C = 0.0625$ and $\sigma = 0.4$, the area of the circle within which eigenvalues are contained increases to keep the density of eigenvalues constant.

Note that the expected distribution of eigenvalues increases so that the threshold $\Re = 0$ is exceeded. Below, system size is increased to $S = 500$. 

Finally, $S = 1000$ is shown below. Again, the density of eigenvalues per unit remains constant at ca 2, but the system has increased in complexity such that some real components of eigenvalues are almost assured to be greater than zero.
