We show that perturbations of massless fields in the Kerr black hole background enjoy a hidden $SL(2,\mathbb{R}) \times U(1)$ (“Love”) symmetry in the properly defined near zone approximation. Love symmetry mixes IR and UV modes. Still, this approximate symmetry allows us to derive exact results about static tidal responses. Generators of the Love symmetry are globally well defined and have a smooth Schwarzschild limit. Generic regular solutions of the near zone Teukolsky equation form infinite-dimensional $SL(2,\mathbb{R})$ representations. In some special cases ($\ell$ parameter is an integer), these are highest weight representations. This is the situation that corresponds to vanishing Love numbers. In particular, static perturbations of four-dimensional Schwarzschild black holes belong to finite-dimensional representations. Other known facts about static Love numbers also acquire an elegant explanation in terms of the $SL(2,\mathbb{R})$ representation theory.

1. INTRODUCTION

The LIGO detection of gravitational waves [1] from inspiralling black hole binaries opened an era of precision black hole physics. The worldline effective theory [2–4] provides an efficient modern toolbox for analytical calculations of the waveforms from binary inspirals and for interpreting the results. In this framework each of the individual black holes in the binary is treated as a point-like particle. Finite size effects are captured by higher-dimensional operators on the worldline. This approach is analogous to the multipole expansion in electrodynamics. Wilson coefficients in front of operators with a quadratic dependence on external fields are called Love numbers. They characterize black hole tidal responses [5]. Remarkably, static Love numbers, which determine response to time-independent external fields, are found to vanish in four-dimensional Einstein theory both for spherical and spinning black holes [5–11]. In this regard, black holes are called the most rigid objects in the Universe. In the worldline effective field theory context, this implies that all quadratic finite-size operators without time derivatives vanish for black holes, which represents an outstanding naturalness problem in the context of the worldline effective theory [12].

In four dimensions, static Love numbers vanish for perturbing fields of all spins and for an arbitrary multipolar index $\ell$. To add to the puzzle, the situation is far more complicated for higher-dimensional Schwarzschild black holes [8,9]. Static Love numbers are nonzero in higher dimensions for generic multipolar indices $\ell$. However, they do vanish for some special values of $\ell$, and for some other special values they exhibit classical renormalization group running.

This intricate pattern calls for a novel (“Love”) symmetry of black holes which would account for the peculiar behavior of static Love numbers. In this Letter, we identify such a symmetry.

2. NEAR ZONE EXPANSION

We start with the simplest case of a massless scalar field $\varphi$ in the Kerr background. The resulting Klein–Gordon equation is known to be separable in the Boyer–Lindquist coordinates. After writing

$$\varphi = \Phi(t, r, \phi)S(\theta) = R(r)S(\theta)e^{-i\omega t + im\phi}$$

one arrives at the spin weight $s = 0$ Teukolsky equation [13] for the radial function,

$$\partial_r \left( \Delta \partial_r R \right) + (V_0 + \epsilon V_1) R = \ell(\ell + 1)R,$$
where
\[ V_0 = \frac{(2Mr_+)^2}{\Delta} \left( (\omega - \Omega m)^2 - 4\omega \Omega m \frac{r - r_+}{r_+ - r_-} \right), \quad (3) \]
\[ V_1 = \frac{2M(\omega a m + 4M^2 r_+^2)}{r_+(r - r_-)} + \omega^2 (r^2 + 2Mr + 4M^2), \quad (4) \]
and we have introduced
\[ \beta = \frac{4Mr_+}{r_+ - r_-}, \quad (5) \]
and \(\ell(\ell + 1)\) is the eigenvalue of the angular operator (A2), while \(\Omega = a/2Mr_+\) is black hole’s angular velocity. Note that, in general, \(\ell\) is not an integer. Here, \(\epsilon\) is a formal parameter of the near zone expansion. For the physical Kerr background \(\epsilon = 1\), while throughout this Letter we are working in the leading near zone approximation, \(\epsilon = 0\). As follows from (4), the leading near zone approximation is accurate provided
\[ \omega r \ll 1, \quad M \omega \ll 1. \quad (6) \]
The range of validity of the near zone approximation covers the near horizon region \(r \gtrsim r_+\) and overlaps with the asymptotically flat region \(r \gg r_+\).

It is important to note that the near zone expansion is different from the low frequency expansion because one keeps some frequency dependent terms in the Teukolsky equation even at the leading order in the near zone expansion. Nevertheless, it provides an accurate approximation at low frequencies. In particular, the leading near zone approximation produces exact answers for \(\omega = 0\) quantities, such as static tidal responses.

Related to this, there is an ambiguity in how one defines the near zone expansion associated with a freedom to move \(\omega\) dependent terms between \(V_0\) and \(V_1\) as soon as \(V_1\) stays finite at the horizon. Other choices of the near zone split can be found in, e.g., [14–16].

3. LOVE SYMMETRY

The reason for our choice is related to the following crucial observation. Let us consider three vector fields of the form
\[ L_0 = -\beta \partial_t, \]
\[ L_{\pm 1} = e^{\pm \beta^{-1} t} \left( \mp \Delta^{1/2} \partial_r + \beta \partial_t (\Delta^{1/2}) \partial_t + \frac{a}{\Delta^{1/2}} \partial_{\phi} \right). \quad (7) \]
It is straightforward to check that these fields satisfy the \(SL(2, \mathbb{R})\) algebra,
\[ [L_n, L_m] = (n - m)L_{n+m}, \quad n, m = -1, 0, 1. \quad (8) \]
Using the quadratic Casimir of this algebra
\[ C_2 \equiv L_0^2 - \frac{1}{2}(L_{-1}L_1 + L_1L_{-1}) \quad (9) \]
one finds that the \(\epsilon = 0\) Teukolsky equation can be written as
\[ C_2 \Phi = \ell(\ell + 1) \Phi. \quad (10) \]
Eigenvalues of the operator \(L_0\) are given by
\[ L_0 \Phi = i\beta \omega \Phi \equiv h \Phi. \quad (11) \]
By transforming into advanced or retarded coordinates it is straightforward to check that all three \(SL(2, \mathbb{R})\) generators are regular at the black hole horizon. As a result, regular solutions of the near zone Teukolsky equation form \(SL(2, \mathbb{R})\) representations even though the symmetry is “hidden”—it does not correspond to an isometry of the background. We will refer to this hidden symmetry as the Love symmetry.

The above properties of the Love symmetry can be contrasted with the noncritical Kerr/CFT proposal [16]. It was observed there that, for a different choice of the near zone split, the leading order Teukolsky equation enjoys a local hidden \(SL(2, \mathbb{R})_L \times SL(2, \mathbb{R})_R\) conformal symmetry. However, the corresponding vector fields are not well defined globally, because they do not respect the \(\phi \to \phi + 2\pi\) periodicity. As a result, regular solutions of the Teukolsky equation do not form \(SL(2, \mathbb{R})_L \times SL(2, \mathbb{R})_R\) representations.

Furthermore, the Love symmetry generators (7) have a smooth Schwarzschild limit, which is not the case for the Kerr/CFT \(SL(2, \mathbb{R})_L \times SL(2, \mathbb{R})_R\). At \(a = 0\) vector fields (7) reduce to the ones derived previously in [17].

These considerations suggest that the Love symmetry (7) may be a better starting point for a holographic description of Kerr black holes. This expectation is further supported by the observation that the \(SL(2, \mathbb{R}) \times U(1)\) symmetry which we found (where the \(U(1)\) factor corresponds to axial rotations) matches the near horizon isometry of the extreme Kerr solution [18, 19]. A nonextreme Kerr black hole may be considered as an excitation above the leading Regge trajectory populated by extreme Kerr
states\textsuperscript{2}. From this viewpoint, it is natural to identify
the hidden Love symmetry (7) with the $SL(2,\mathbb{R})$ isom-
metry of the extreme near horizon region. In an excited
nonextreme state this symmetry gets spontaneously bro-
ken and, thus, ceases to be an isometry.

4. HIGHEST WEIGHT BANISHES LOVE

To illustrate the power of the Love symmetry, let us
apply it to explain properties of static Love numbers. To
define them, one looks at the large-$r$ behavior of the static
radial solution $R(r)$ with a fixed growing asymptotics, de-
termined by a source at spatial infinity. Love numbers
are defined as coefficients in front of decaying powers in
this asymptotic expansion. For black holes in four dimen-
sional general relativity this radial solution turns out to
turns out to

Furthermore, note that, at the leading order in the
near zone expansion, the angular equation (A2) turns
into the standard equation for the associated Legendre
polynomials, and hence, $\ell$ is a positive integer\textsuperscript{3}, satisfying
$\ell \geq |m|$. This suggests that static Schwarzschild pertur-
bations, which have $h = 0$, belong to a finite-dimensional
representation of the Love symmetry. To prove this, let us
consider the $h = -\ell$ highest weight vector $v_{-\ell,0}$,

\begin{equation}
L_1 v_{-\ell,0} = 0 \, , \quad L_0 v_{-\ell,0} = -\ell v_{-\ell,0} \, .
\end{equation}

By making use of (7), one finds

\begin{equation}
v_{-\ell,0} = e^{\ell \beta^{-1} t} \Delta^{\ell/2} \, ,
\end{equation}

where we set $m = 0$ without loss of generality. As a
consequence of the $SL(2,\mathbb{R})$ commutation relations $v_{-\ell,0}$
solves the Teukolsky equation (10). By transforming into
advanced or retarded coordinates, one finds that this so-
lution is regular at the black hole horizon.

As an aside, it is worth noting that conventionally one
ensures regularity of the solutions to the Teukolsky equa-
tion by enforcing the incoming wave condition at the hori-
zon [13, 21]. However, this criterion may fail for purely
imaginary frequencies, which is the case for $v_{-\ell,0}$. In
particular, the lowest weight vector $\bar{v}_{\ell,0}$ satisfying

\begin{equation}
L_{-1} \bar{v}_{\ell,0} = 0 \, , \quad L_0 \bar{v}_{\ell,0} = \ell \bar{v}_{\ell,0} \, ,
\end{equation}

takes form

\begin{equation}
\bar{v}_{\ell,0} = e^{-\ell \beta^{-1} t} \Delta^{\ell/2}
\end{equation}

and also provides us a regular at the horizon solution of
(10). Regularity of both (13) and (15) is counterintuitive
from the viewpoint of the incoming wave condition. Nev-

ertheless, both solutions are regular as can be checked by
transforming to the advanced or retarded coordinates.

One may obtain the rest of the representation by act-
ing on the highest weight vector $v_{-\ell,0}$ with the lowering
operator $L_{-1}$, which increases $h$ by unity. This way one
arrives at the static solution with $h = 0$ given by

\begin{equation}
v_{-\ell,\ell} = L_{-1}^\ell v_{-\ell,0} \, .
\end{equation}

Since the highest weight vector $v_{-\ell,0}$ and $L_{-1}$ are both
regular at the horizon, the same is true for $v_{-\ell,\ell}$ and
all other states in the multiplet. Now we can use the
$SL(2,\mathbb{R})$ algebra in the opposite direction. We take the
static solution $v_{-\ell,\ell}$ and climb up to the highest weight
state by applying $\ell$ times the raising operator $L_{+1}$, i.e.
$v_{-\ell,0} \propto L_{+1}^\ell v_{-\ell,\ell}$. But the highest weight vector itself is
annihilated by $L_{+1}$,

\begin{equation}
L_{+1}^{\ell+1} v_{-\ell,\ell} \propto L_{+1} v_{-\ell,0} = 0 \, .
\end{equation}

Additionally, it follows from (7) that

\begin{equation}
L_{+1}^{\ell+1} v(r) = (-1)^{\ell+1} e^{(\ell+1)\beta^{-1} t} \Delta^{\ell+1} \partial_\phi^{\ell+1} v(r) \, ,
\end{equation}

for any function $v(r)$ independent of $t$ and $\phi$. Then
Eq. (16) dictates that the static solution $v_{-\ell,\ell}$ is an $\ell$-
th degree polynomial in $r$. Given that the corresponding

\textsuperscript{2} Recently, an analogous approach proved to be very useful for
understanding the spectrum of Yang-Mills glueballs [20].

\textsuperscript{3} Of course, in the Schwarzschild case this is true without taking
the near zone limit.
Love number is defined as a coefficient in front of $r^{-\ell-1}$ in the $r \to \infty$ expansion of $v_{-\ell,0}$, we conclude that scalar static Love numbers of Schwarzschild black holes all vanish as a consequence of the $SL(2, \mathbb{R})$ algebra. This result is exact even though this derivation has been performed at the leading order in the near zone expansion.

Note that we could also have obtained a static regular solution with the same value of $\ell$ by acting with $L_1^\ell$ on the lowest weight vector $\vec{v}_{\ell,0}$. From the uniqueness of the regular solution, it follows, then, that $\vec{v}_{\ell,0}$ belongs to the same $SL(2, \mathbb{R})$ representation,

$$\vec{v}_{\ell,0} \propto L_{-1}^{2\ell} v_{-\ell,0} \equiv v_{-\ell,2\ell}. \quad (18)$$

This implies that the dimensionality of the corresponding representation is finite and is equal to $2\ell + 1$.

A large part of this argument proceeds unchanged for a rotating black hole. The first step is to look for the highest weight vector $v_{-\ell,0}(m)$. Using (7) one finds

$$v_{-\ell,0}(m) = e^{\ell \beta^{-1} + im\phi} \frac{(r - r_+)^{m+2/\ell}}{(r - r_-)^{m+2/\ell}}, \quad (19)$$

which is, again, regular at the horizon. Hence, the descendant vector $v_{-\ell,0}(m)$ is, again, a regular static solution annihilated by $L_1^{\ell+1}$. The complication is that $v_{-\ell,0}(m)$ now depends on $\phi$, so a generalization of (17) is required. Inspecting the explicit expression for $L_1$ in (7) suggests the following ansatz for $v_{-\ell,0}(m)$,

$$v_{-\ell,0}(m) = e^{im\phi} \mathcal{F}(r)v(r), \quad (20)$$

where

$$\mathcal{F}(r) = \frac{(r - r_+)^{m+2/\ell}}{(r - r_-)^{m+2/\ell}}. \quad (21)$$

Indeed, then, one finds that

$$L_1^{\ell+1} e^{im\phi} \mathcal{F}(r)v(r) = (-1)^{\ell+1} e^{(\ell+1)\beta^{-1}t} \mathcal{F}(r) \Delta \frac{\ell+1}{2} \partial_r^{\ell+1} v(r), \quad (22)$$

again implying that $v(r)$ is a degree $\ell$ polynomial in $r$. This result agrees with the brute force solution of the Teukolsky equation, which results in the explicit expression for $v(r)$ in terms of a hypergeometric function (see, e.g., [11]).

Naively, the expression (20) suggests the presence of a nontrivial tidal response associated with the nonpolynomial form factor (21). However, as explained in [10, 11], this response can be attributed to frame dragging. It is purely dissipative and does not correspond to an effect of local worldline operators. The static Love numbers are still zero. An intuitive way to see this is to notice that the form factor (21) disappears completely if one were to perform a transform into the advanced coordinates. If we were to perform the calculation in the advanced coordinates to start with, as was advocated in [22], the result would be purely polynomial.

Note that, unlike (13), the highest weight vector (19) is regular only at the future (black hole) horizon. It is zero at the past (white hole) horizon and exhibits a branch point singularity there. This is acceptable physically in the response calculations [13], because the white hole horizon of an eternal black hole is never present for physical black holes formed as a result of a collapse. This also clarifies a physical meaning of the prefactor (21)—it signals the presence of a singularity at the white hole horizon. In this case, static solutions belong to infinite-dimensional highest weight $SL(2, \mathbb{R})$ representations ("Verma modules")—the lowest weight vector $\vec{v}_{\ell,0}(m)$ is singular at the future horizon at $\Omega m \neq 0$ (and regular at the white hole horizon) and, thus, belongs to a different representation.

To summarize, we see that the $SL(2, \mathbb{R})$ representation theory provides an elegant algebraic characterization for the properties of the static Love numbers. Vanishing Love numbers correspond to highest weight $SL(2, \mathbb{R})$ representations. In general, these are infinite dimensional, which corresponds to a singularity at the white hole horizon. Finite-dimensional representations (which necessarily exhibit highest and lowest weight properties simultaneously) arise when the corresponding solutions are regular at the horizon both in advanced and retarded coordinates.

5. GENERALIZATIONS

Remarkably, the puzzling properties of static Love numbers for higher-dimensional Schwarzschild black holes can also all be nicely phrased in terms of the representation theory. Spherical higher-dimensional black holes also exhibit a hidden $SL(2, \mathbb{R})$ symmetry [17]. Its generators are summarized in Appendix B. The near zone Teukolsky equation now takes the following form in $d$ spacetime dimensions,

$$C_2 \Phi = \hat{\ell} (\hat{\ell} + 1) \Phi, \quad \text{with} \quad \hat{\ell} = \frac{\ell}{d-3}. \quad (23)$$
For integer values of $\ell$ one again arrives at finite-dimensional $SL(2, \mathbb{R})$ representations. This is exactly the case when the static Love numbers were shown to vanish [8, 9].

Generically, $\ell$ is not an integer, the corresponding representations do not have the highest weight form and Love numbers do not vanish. Still, the $SL(2, \mathbb{R})$ representation theory explains why these Love numbers do not exhibit logarithmic running. The point is that generically singular and regular solutions of the Teukolsky equation correspond to different $SL(2, \mathbb{R})$ representations. This provides a local criterion for selecting the regular one and excludes the possibility of renormalization group running.

This argument breaks down at half-integer $\ell$’s. As $\ell$ approaches a half-integer value, $SL(2, \mathbb{R})$ representations describing regular and singular solutions become the same (see Chapter VII of [23]). This makes it impossible to distinguish them locally and leads to a classical renormalization group running of Love numbers for half-integer $\ell$’s [8, 9]. It appears that a proper analogy for this phenomenon is a resonance condition required for the logarithmic running to appear in conformal perturbation theory, c.f. [24, 25].

The arguments above can be straightforwardly extended to other bosonic fields in four dimensions. We provide the details in [26] and present just a short summary here. The generalization of the generators (7) for a generic massless field of spin weight $s$ is given by

$$L_0^{(s)} = L_0 + s,$$
$$L_{\pm 1}^{(s)} = L_{\pm 1} - se^{\pm 1}(1 \pm 1)\partial_r(\Delta^{1/2}).$$

The corresponding quadratic Casimir satisfies the spin weight $s$ Teukolsky equation [13, 27] in the near zone approximation$^4$,

$$C_2^{(s)} \psi_s = \left( C_2 + s(\partial_r \Delta)\partial_r + s^2 \frac{2Mr_+ (r_+ - r_-)}{\Delta} \partial_t + 2s \frac{(r - M)}{\Delta} a \partial_\phi + s^2 + s \right) \psi_s = \ell(\ell + 1) \psi_s,$$  

where $\psi_0 = \Phi$ is a test scalar field, $\psi_{\pm 1}$ are the Newman-Penrose-Maxwell scalars, from which one can extract the electromagnetic field around the black hole [13], and $\psi_{\pm 2}$ are the Newman-Penrose-Weyl scalars that can be used to reconstruct gravitational perturbations [13, 30, 31].

6. INFINITE EXTENSION OF LOVE

Very general arguments [32] suggest that the $SL(2, \mathbb{R}) \times U(1)$ symmetry discussed so far is just a small part of a full infinite-dimensional algebra. Note that the proof of [32] does not apply here directly, because it relies on unitarity, and the representations encountered above are all nonunitary. Nevertheless, there are indications that $SL(2, \mathbb{R}) \times U(1)$ discussed here is, indeed, a part of a much larger algebraic structure. We will explore this structure in a future work [26] and present just a few preliminary remarks here.

The main observation is that the near zone expansion considered by Starobinsky [14] also exhibits a hidden $SL(2, \mathbb{R})$ symmetry. The corresponding $SL(2, \mathbb{R})$ generators take the following form

$$J_a = L_a + \Omega \beta v_{0,a} \partial_\phi,$$  

where

$$v_{0, \pm 1} = e^{\pm 1} \left( \frac{r - r_+}{r - r_-} \right)^{1/2},$$  
$$v_{0,0} = -1.$$

This near zone expansion is less suited for demonstrating vanishing of static Love numbers at $\Omega m \neq 0$, but appears to have other particularly nice properties. For instance, arguments analogous to the ones presented above, prove that in the Starobinsky near zone approximation the black hole response vanishes at the locking frequency $\omega = m\Omega$. Furthermore, explicit calculations demonstrate that in this approximation all nonstatic Love numbers vanish as well, which can also be proven algebraically [26].

Note that by acting on $v_{0,a}$ with the $SL(2, \mathbb{R})$ genera-

$^4$ As in the $s = 0$ case discussed above, this near zone split is slightly different from the one used in Refs. [28, 29].
tors (7) one obtains vectors
\[v_{0,n} = L_{-1}^{-n-1}v_{0,1} = (-1)^{n-1}(n-1)!e^{-\beta^{-1}i}(r - r_+ \over r - r_-)^{n/2},\]
\[v_{0,-n} = L_1^{-n-1}v_{0,-1} = (n-1)!e^{\beta^{-1}i}(r - r_+ \over r - r_-)^{n/2},\]
where \(n > 0\). Vectors \(v_{0,k}\) with \(k \in \mathbb{Z}\) are all regular at the past and future horizons and span an \(SL(2,\mathbb{R})\) representation \(V\) with zero Casimir,
\[C_2(V) = 0.\]
These considerations suggest that it is natural to consider an infinite-dimensional extension of the Love symmetry into a semidirect product \(SL(2,\mathbb{R}) \ltimes U(1)_V\), where \(U(1)_V\) are vector fields of the form \(v\partial_{\phi}\), with \(v \in V\). The near zone considered here and the one by Starobinsky correspond to different \(SL(2,\mathbb{R})\) subalgebras of this larger algebra.

7. DISCUSSION AND FUTURE DIRECTIONS

The presented results open numerous new avenues for future research both on a purely theoretical side, and as far as relations to gravitational wave observations are concerned. On a theory side, it is very satisfactory that the "Love hierarchy problem" has led us to a novel symmetry. Static Love numbers vanish as a consequence of this symmetry. At first sight, everything is now consistent with the 't Hooft notion of naturalness [33].

Note that the Love symmetry has an unconventional property that it mixes UV and IR modes. Indeed, due to the presence of the \(e^{\pm \beta^{-1}i}\) factors in \(L_{\pm 1}\) generators, \(SL(2,\mathbb{R})\) multiplets contain both the static solution and high frequency modes. However, only in the near extreme limit \(\beta^{-1}M \ll 1\) the action of the Love symmetry is compatible with the near zone conditions (6). This does not invalidate any of our arguments. Our logic is first to take the near zone limit \(\epsilon = 0\), which provides accurate results for low frequency observables, and then to solve the resulting theory exactly. This allows us to benefit from the presence of the Love symmetry in spite of the UV/IR mixing introduced by \(L_{\pm 1}\) generators. Still, it is somewhat unclear whether this should be considered as a triumph of naturalness in the sense of 't Hooft, or rather an example of the "UV miracle." It remains to be seen whether this unconventional example may provide useful lessons for other famous hierarchy problems.

It is a popular slogan nowadays that "black holes are the hydrogen atom of 21st century", see, e.g., [34, 35]. We see that this comparison is actually accurate in a very concrete technical sense. Low energy dynamics of both systems is governed by an emergent integrable algebraic structure. It is still natural to wonder who ordered these structures. What are the reasons for the \(SO(4)\) Laplace–Runge–Lentz symmetry of the hydrogen atom from the viewpoint of the full quantum electrodynamics and for the Love symmetry of black holes from the viewpoint of the full general relativity? We are not aware of a good answer in the hydrogen case, but it looks plausible that, for black holes, the horizon is the culprit. We already saw that nonzero static Love numbers for higher-dimensional black holes do not signal the loss of symmetry. It will be interesting to study what happens in other examples, such as in the presence of higher-derivative corrections to the Einstein action, c.f. [36].

Other next natural steps in theoretical studies of the Love symmetry include a comprehensive analysis of its algebraic structure, understanding its relation to near horizon isometries in the extreme limit and to the asymptotic Bondi–Metzner–Sachs symmetries, and inclusion of massive fields. It will also be interesting to see whether unitary \(SL(2,\mathbb{R})\) representations play any special role in this story.

At the same time, it is important to remember that the study of black hole responses is far from being a pure theorist’s exercise. These effects contribute to gravitational waveforms of binary inspirals, and the corresponding Wilson coefficients will be probed by the forthcoming gravitational wave observations [12, 37]. An approximate hidden symmetry provides an extremely valuable addition and a useful organizing principle to the effective field theory toolbox. Chiral symmetry of pion interactions is one of the most famous and successful illustrations of this. Similar to the pion case, it is important to systematically work out all consequences of the Love symmetry, including the ones beyond the strict static limit. To achieve this it should be fruitful to replace low frequency expansion with the near zone expansion. By treating the symmetry breaking parameters in (4) as spurions under the Love symmetry, it should be possible to obtain analogues of the Gell-Mann–Okubo relations for finite frequency responses and quasinormal modes.

discussions. This work is supported in part by the NSF award PHY-1915219 and by the BSF grant 2018068. MI is partially supported by the Simons Foundation’s Origins of the Universe Program.

Appendix A: Conventions for the Kerr metric

The Kerr metric in the Boyer–Lindquist coordinates takes the following form

$$\begin{align*}
\text{d}s^2 &= -\left(1 - \frac{2Mr}{\Sigma}\right)\text{d}t^2 - \frac{4Mar\sin^2\theta}{\Sigma}\text{d}t\text{d}\phi + \frac{\Sigma}{\Delta}\text{d}r^2 \\
&\quad + \Sigma\text{d}\theta^2 + \sin^2\theta\left(r^2 + a^2 + \frac{2Ma^2r\sin^2\theta}{\Sigma}\right)\text{d}\phi^2,
\end{align*}$$

where $M$ is the black hole mass, $0 < a < M$ is the reduced spin parameter and

$$\Delta = r^2 - 2Mr + a^2, \quad \Sigma = r^2 + a^2\cos^2\theta.$$ 

Two roots of $\Delta$ correspond to the outer $r_+$ and the inner $r_-$ black hole horizons. The horizon angular velocity is defined as

$$\Omega = \frac{a}{2Mr_+}.$$ 

After the variable separation (1) the angular eigenfunctions satisfy [27]

$$\left(-\frac{1}{\sin\theta}\partial_\theta\sin\theta\partial_\theta + \frac{m^2}{\sin^2\theta} + \epsilon a^2\omega^2\sin^2\theta\right)S = \ell(\ell + 1)S,$$

where $\epsilon$ is the near zone expansion parameter.

Appendix B: Higher dimensions

$SL(2,\mathbb{R})$ symmetry of the near zone Teukolsky equation for a Schwarzschild $d$-dimensional black hole has been constructed in [17]. Its generators take the following form

$$L_0 = -\beta\partial_t, \quad L_\pm = e^\pm\beta\text{e}^{-t}\left(\pm\Delta_p^{1/2}\partial_\rho + \beta\partial_\rho\Delta_p^{1/2}\partial_t\right),$$

with $\rho = r^{d-3}$, $\Delta_\rho = \rho(\rho - i_+^{d-3})$ and

$$\beta = \frac{2r_+}{d-3}, \quad r_+ = \frac{8\pi\Gamma((d-2)/2)M}{(d-2)\pi^2}.$$ 

The Klein-Gordon equation in the near zone can be written using the corresponding quadratic Casimir as

$$\mathcal{C}_2\Phi = \left(\partial_\rho\Delta_\rho\partial_\rho - \frac{r_+^{2d-4}}{(d-3)^2\Delta_\rho}\partial_t^2\right)\Phi = \hat{\ell}(\ell + 1)\Phi,$$

where $\hat{\ell} \equiv \ell/(d-3)$.
