Improper ferroelectricity and multiferroism in 2H-BaMnO$_3$

Julien Varignon$^1$ and Philippe Ghosez$^1$

(Dated: February 11, 2013)

Using first-principles calculations, we study theoretically the stable 2H hexagonal structure of BaMnO$_3$. We show that from the stable high temperature P6$_3$/mmc structure, the compound should exhibit an improper ferroelectric structural phase transition to a P6$_3$cm ground state. Combined with its antiferromagnetic properties, 2H-BaMnO$_3$ is therefore expected to be multiferroic at low temperature. The phase transition mechanism in BaMnO$_3$ appears similar to what was reported in YMnO$_3$ in spite of totally different atomic arrangement, cation sizes and Mn valence state.

Multiferroic compounds combining ferroelectric and (anti-)ferromagnetic orders present both fundamental and technological interests and have been the topic of intensive researches during the last decade$^{1-3}$. The identification of new single-phase multiferroics has been particularly challenging. In this search, a special emphasis was placed on the family of multifunctional ABO$_3$ compounds within which belong many popular ferroelectric and magnetic materials. Unfortunately, few multiferroic ABO$_3$ oxides have been identified to date. This scarcity was justified in terms of typical antagonist metal d-state occupancy requirements$^5$: on the one hand, ferroelectricity in typical compounds like BaTiO$_3$ arises from the hybridization between occupied O 2p orbitals and empty Ti 3d states and requires d$^0$-ness while, on the other hand, magnetism requires partial d orbitals occupancy, so that ferroelectricity and magnetism often appear to be mutually exclusive.

Exceptions to this rule exist however. In the antiferromagnetic CaMnO$_3$ perovskite, a ferroelectric instability exists in spite of partial d-state occupancy. In bulk samples, this instability is suppressed by antiferrotordistortive oxygen motions but it was predicted theoretically$^6$, and recently confirmed experimentally$^7$, that CaMnO$_3$ can be made ferroelectric, and de facto multiferroic, under appropriate tensile epitaxial strain. In the same spirit, it was proposed that, due to its larger volume, the perovskite form of BaMnO$_3$ should develop a ferroelectric antiferromagnetic ground state$^8$.

BaMnO$_3$ does however not naturally crystallize in the perovskite structure with corner-sharing oxygen octahedra. Due to its large Goldschmidt tolerance factor, it stabilizes instead in a hexagonal 2H structure with face-sharing oxygen octahedra (Figure 1(a)). Increasing pressure decreases the hexagonal character, yielding at high pressure various possible forms including a 4H hexagonal structure combining corner- and face-sharing octahedra, which is intermediate between 2H and cubic perovskite structures$^9$. The stability of the 2H structure was confirmed from first-principles calculations$^{10,11}$ but its exact symmetry remains under debate.

From the similarity of spectra with BaNiO$_3$,$^{12}$ Hardy originally assigned the 2H phase of BaMnO$_3$ at room temperature to the polar P6$_3$mc space group$^8$. Combined Raman and infra-red phonon measurements performed by Roy and Budhan$^{12}$ are compatible with such a polar character, that is also in line with a recent report of room temperature ferroelectricity in 2H – BaMnO$_3$ by Satapathy et al.$^{13}$.

Nevertheless, Christensen and Ollivier reported that 2H-BaMnO$_3$ should better belong to the P6$_3$/mmc space group$^{14}$. We notice that a similar re-assignment to P6$_3$/mmc was also proposed for BaNiO$_3$,$^{15}$ that had served as reference material to Hardy. This was also the choice of Cussen and Battle$^{16}$ who found no clear evidence to assign the room temperature structure of 2H-BaMnO$_3$ to the polar P6$_3$mc space group but instead chose the non-polar P6$_3$/mmc space group. Going further, they highlighted a structural phase transition between room temperature and 80 K to a polar P6$_3$cm space group, yielding unit-cell tripling. Moreover, while Christensen and Ollivier$^{12}$ were not observing any clear magnetic order above 2.4 K, Cussen and Battle$^{16}$ reported an antiferromagnetic ordering below $T_N = 59K$ in the P6$_3$cm phase, with neighboring spins antiferromagnetically coupled along the polar axis and forming a triangular arrangement perpendicular to it. Although it was not explicitly emphasized, according to this, BaMnO$_3$ should be multiferroic at low temperature in its stable 2H polymorph. Nevertheless this has to be taken with caution since Cussen and Battle cannot rule out the possibility of a centrosymmetric P3c1
space group (subgroup of $P6_3/mcm$) at low temperature. Also, no consensus has been achieved yet regarding the stable structure at room temperature.

In order to get additional insight into the possible ferroelectric nature of $2H$ – BaMnO$_3$, we performed first-principles calculations. We show that the high-temperature phase should belong to the $P6_3/mmc$ space group and that the compound should undergo an improper ferroelectric structural phase transition to a $P6_3/cm$ phase, through a mechanism similar to what happens in hexagonal YMO$_3$. Combined with its antiferromagnetic properties, this study confirms that $2H$ – BaMnO$_3$ should be multiferroic at low temperature.

Our calculations have been performed within density functional theory (DFT) using the CRYSTAL09 package. We used the B1-WC hybrid functional that was previously found appropriate for the study of multiferroic oxides. Relativistic pseudopotentials and a $3\zeta$ valence basis sets were used for the barium atoms. Small core Hay-Wadt pseudopotentials, associated with $2\zeta$ valence basis sets, were used for the manganese atoms. All-electron $2\zeta$ basis sets, specifically optimized for $O^{2-}$, were used for the oxygen atoms. The calculations were carried out on a $4\times8\times4$ $k$-point grid for the tripled unit cell (30 atoms). The polarization was computed from the displacement of Wannier function centers. We worked within a collinear-spin framework assuming an A-type antiferromagnetic order with spins antiparallel along the $c$ direction and aligned in the $(a, b)$ plane. Calculations with a ferromagnetic ordering provided similar results. We performed geometry optimization of atomic positions until the root mean square values of atomic forces were lower than $5 \times 10^{-5}$ Ha/Bohr$^{-1}$ and until the root mean square of atomic displacements were lower than $5 \times 10^{-5}$ Bohr. For better comparison with the experiment, results reported below have been obtained at fixed experimental lattice parameters as reported by Cussen and Battle at room temperature. Similar results have been obtained adopting the lattice parameters reported at 1.7 K and 80 K. Full structural optimization including lattice parameters were also performed providing qualitatively similar results but yielding a smaller ferroelectric distortion, due to small theoretical errors on the lattice parameters.

First, we performed a structural optimization of $2H$ – BaMnO$_3$ starting from a polar $P6_3/mmc$ configuration as initially proposed by Hardy. Surprisingly, the system went back to a $P6_3/mmc$ configuration, with atomic positions (one degree of freedom, $x_O = 0.1473$) in good agreement with what was reported by Cussen and Battle ($x_O = 0.1495$). This demonstrates theoretically that the system does not want a priori to be ferroelectrically distorted but prefers to adopt a non-polar $P6_3/mmc$ symmetry as first proposed by Christensen and Ollivier. This is in conflict with the recent claim of a room temperature $P6_3mc$ ferroelectric phase by Satapathy et al. However the crystal structure they report corresponds in fact to a $P6_3/mmc$ phase and is therefore inconsistent with the polarization they measure. In order to further confirm our result, we computed the zone-center phonon modes of the relaxed $P6_3/mmc$ phase without identifying any zone-center unstable mode, the lowest polar $\Gamma_2$-mode being at a frequency around 56 cm$^{-1}$.

In order to test the possibility of a phase transition to a $P6_3/cm$ or a $P3c1$ phase, we computed the phonons at the zone-boundary point $q=(1/3, 1/3, 0)$. In this case, we identified an unstable mode at 52 cm$^{-1}$ of $K_3$ symmetry. This mode is related to oxygen and manganese motions along the polar axis. Its condensation produces a unit-cell tripling and brings the system into the $P6_3/cm$ symmetry. We notice that no unstable mode of $K_3$ symmetry is identified, ruling out the possibility of a transition to a phase of $P6_3/mcm$ or $P3c1$ symmetry.

Atomic relaxation of the $P6_3/cm$ phase has been performed, yielding a gain of energy of 21 meV/f.u. respect to the $P6_3/mmc$ structure. The relaxed atomic positions are reported in Table I and show qualitative agreement with experimental data. BaMnO$_3$ appears in our hybrid functional calculation as an insulator with an electronic bandgap of 4.15 eV. As allowed by the polar nature of the $P6_3/cm$ space group, this phase also develops a sizable spontaneous polarization $P_s = 0.92 \mu C cm^{-2}$ along the polar axis. Since this polarization can be either up or down (and is so a priori switchable), this phase can be labelled as ferroelectric.

Interestingly, although the condensation of the $K_3$ mode breaks inversion symmetry, this mode is non-polar (i.e. its mode effective charge is zero) and its condensation alone does not induce any significant polarization.

TABLE II. Amplitude (in Å) of symmetry allowed displacements for experimental and theoretical structures (at fixed lattice parameters).
Further insight into the mechanism yielding a significant polarization at the phase transition from $P6_3/mmc$ to $P6_3cm$ is therefore needed and can be obtained from a decomposition of the atomic distortion condensed at the transition into symmetry adapted modes, as achievable with the Amplimodes software of the Bilbao Crystallographic server.\cite{27,28}

The results of this decomposition are reported in Table 3. Both theory and experiment find the structural distortions can be better understood from an expansion of the atomic distortion condensed at the $P6_3/mmc$ phase in terms of their amplitude $Q_{K_3}$ and $Q_{\Gamma_2}$:

$$F(Q_{K_3}, Q_{\Gamma_2}) = \alpha_{20}Q_{K_3}^2 + \alpha_{22}Q_{\Gamma_2}^2 + \beta_{20}Q_{K_3}^4 + \beta_{22}Q_{\Gamma_2}^4 + \beta_{31}Q_{K_3}Q_{\Gamma_2}^3 + \beta_{22}Q_{K_3}Q_{\Gamma_2}^2$$

(1)

The coefficients of this energy expansion were determined from DFT calculations on a $\sqrt{3}a_{PE} \times \sqrt{3}b_{PE} \times c_{PE}$ optimized $P6_3/mmc$ supercell with various amplitudes of $Q_{K_3}$ and $Q_{\Gamma_2}$ condensed. The results are summarized in Fig. 2 and are consistent with what was previously discussed. The $\Gamma_2$ polar mode is stable and associated to a single well while the $K_3$ mode is unstable and has a typical double-well shape.

The phase transition of 2H-BaMnO$_3$ from $P6_3/mmc$ to $P6_3cm$ is therefore clearly driven by the unstable $K_3$ primary mode. Then the sizable polarization arises from the additional condensation of the stable polar $\Gamma_2$ secondary mode which, as further illustrated in Fig. 3, results from a progressive shift of the minimum of the single well, produced by $Q_{K_3}$ through the $\beta_{31}Q_{K_3}^3Q_{\Gamma_2}$ coupling term.

![FIG. 2. Evolution of the energy (in meV) of 2H-BaMnO$_3$ in terms of the amplitude $Q_{K_3}$ and $Q_{\Gamma_2}$ (in fractional units) of the $K_3$ and $\Gamma_2$ modes. The $P6_3/mmc$ structure was taken as reference.](image)

![FIG. 3. Energy (in meV) as a function of $\Gamma_2$ allowing displacements at fixed $Q_{K_3}$ (in fractional units).](image)

![FIG. 4. Spontaneous polarization (in $\mu C/cm^2$) as a function of the primary order parameter $Q_{K_3}$ (in fractional units).](image)

This mechanism is similar to what was reported by Fennie and Rabe\cite{29} in YMnO$_3$ and allows us to identify 2H-BaMnO$_3$ as an improper ferroelectric. The evolution of the polarization with $Q_{K_3}$ is represented in Fig. 3. We first notice that the polarization estimated within the model from the amplitude of $Q_{\Gamma_2}$ assuming constant Born effective charges ($Z^{\text{eff}}_{\text{Ba}} = +2.10e$, $Z^{\text{eff}}_{\text{Mn}} = +6.45e$ and $Z^{\text{eff}}_{\text{O}} = -2.85e$ along the $c$ axis in the $P6_3/mmc$ phase) properly reproduces the DFT calculation. As discussed by Fennie and Rabe, two independent regimes can be identified: at small $Q_{K_3}$ amplitude, $Q_{\Gamma_2}$ (and therefore $P_s$) evolves like $Q_{K_3}$ while at larger amplitude it evolves linearly. Contrary to YMnO$_3$ that has its ground state in the linear regime, BaMnO$_3$ is still in the small amplitude regime in our calculation.

Although they both crystallize in the same hexagonal $P6_3/mmc$ space group at high-temperature, the similarity between BaMnO$_3$ and YMnO$_3$ is astonishing. First, the valence state of the cations are different in both compounds (+2/ +4 in BaMnO$_3$ versus +3/ +3 in YMnO$_3$). The cation sizes are also distinct in both compounds.
yielding a Goldschmidt tolerance factor $t > 1$ in BaMnO$_3$ and $t < 1$ in YMnO$_3$. Consequently, the atomic structure is totally different in both compounds: the Mn atom is surrounded by face-sharing oxygen octahedra in BaMnO$_3$ and corner-sharing oxygen trigonal bipyramids in YMnO$_3$. The atomic motion associated to the unstable $K_3$ mode is also rather different. In YMnO$_3$, $K_3$ motions correspond to a tilt of MnO$_3$ bipyramids accompanied by a shift of Y atoms and O atoms forming the basis of MnO$_3$ bipyramids along the polar axis. This leads to a more symmetric environment for the Mn atom, reducing its oxidation degree and making the charge of all O atoms similar. In BaMnO$_3$, the $K_3$ mode is associated only to a shift of Mn and O atoms along the polar axis, increasing the absolute value of the oxidation degree of all atoms. The fact that both compounds exhibit an unstable $K_3$ mode, that can drive improper ferroelectricity appears therefore rather fortuitous.

Finally, we studied the magnetic properties of ground state 2H - BaMnO$_3$. In their seminal work, Christensen and Ollivier did not identify any clear magnetic order above 2.4 K but more recently, Cussen and Battle reported an antiferromagnetic ordering below $T_N = 59 \text{K}$ in the $P6_3cm$ phase: they proposed a configuration comparable to YMnO$_3$ in which neighboring spins are antiferromagnetically aligned along the polar axis and forming a triangular arrangement perpendicular to it.

Although working within a collinear-spin approximation, we estimated the coupling constants $J_{ij}$ between spins at site $i$ and $j$ in the $P6_3cm$ phase through the fit of the Heisenberg effective Hamiltonian limited to nearest-neighbor interactions: $H_{\text{Heisenberg}} = -\sum_{i<j} J_{ij} \vec{S}_i \cdot \vec{S}_j$. 2H-BaMnO$_3$ presents two distinct magnetic interactions: one along the polar axis and one perpendicular to it. We found a strong antiferromagnetic coupling $J_c = -32.77 \text{ meV}$ along the polar axis and a much weaker interchain antiferromagnetic coupling $J_{ab} = -0.14 \text{ meV}$ in plane, comparable to that computed in YMnO$_3$. The estimate of $J_{ab}$ has certainly to be taken with more caution than $J_c$: in YMnO$_3$, collinear-spin calculations significantly underestimated the magnitude of $J_{ab}$ on a similar triangular arrangement of spins (0.59 meV instead of 2.3-3 meV experimentally). Nevertheless, a strong anisotropy of the magnetic interactions seems to be likely and can be explained from simple geometry arguments. Along the polar axis, there are face-sharing octahedra and the super-exchange term between two neighboring Mn atoms goes through three different Mn-O-Mn exchange paths, increasing the overlap between Mn 3d and O 2p orbitals and the magnetic coupling. On the other hand, Mn-Mn interchain distances are longer and the super-exchange term in-plane has to go consecutively through O and Ba atoms (see Fig. 1); the overlap between orbitals will be smaller and the magnetic exchange interactions weaker. So, although it is proposed that both share the same magnetic arrangement, the antiferromagnetic coupling in 2H-BaMnO$_3$ appears substantially different than in YMnO$_3$ for which the strongest magnetic interactions are in-plane.

In summary, we propose in this Letter that 2H-BaMnO$_3$ is an improper ferroelectric. Our calculations moreover confirms its antiferromagnetic character, making it a multiferroic compound amazingly similar to YMnO$_3$, in spite of a radically different atomic arrangement. Improper ferroelectrics have recently generated increasing interest in view of their unusual electrical properties. Not so many ABO$_3$ improper ferroelectrics have been reported yet and our study illustrates that such behavior can also happen in hexagonal 2H compounds. We hope that our theoretical work will motivate the search of new improper ferroelectrics and multiferroics in this class of compounds.
