We study the diluted Ising ferromagnet on the Bethe lattice as a case study for the application of the cavity method to problems with Griffiths-McCoy singularities. Specifically, we are able to make much progress at infinite coupling where we compute, from the cavity method, the density of Lee-Yang zeros in the paramagnetic Griffiths region as well as the properties of the phase transition to the ferromagnet. This phase transition is itself of a Griffiths-McCoy character albeit with a power law distribution of cluster sizes.

I. INTRODUCTION

The Bethe-Peierls or cavity method has a long history in statistical mechanics [1]. The application of this method to disordered systems has recently undergone a considerable revival, mainly in connection with the analysis of typical case complexity of random NP-complete (i.e. difficult) optimization problems. This recent work has led to an improved understanding of the statistical mechanics of disordered systems—in particular to a formulation of the physics of replica symmetry breaking without resorting to replicas. Importantly, it has also led to a new class of algorithms, now known as survey propagation, for the optimization problems [2]. In addition, very recent work [3, 4, 5] has attempted to generalize the cavity method/belief propagation to disordered quantum systems, obtaining encouraging results.

The work alluded to above does not address one striking feature of the physics of disordered systems, namely the presence of Griffiths-McCoy (GM) singularities [6, 7, 8] in their thermodynamics in an applied field. While the form of these singularities can be readily determined from rough estimates of the statistics of the rare regions from which they emanate, their detailed extraction can be a tricky task due to their delicate nature, especially in classical systems. Indeed, in field theoretic formulations they appear as non-perturbative (instanton) effects [9].

In this paper we consider the task of extracting these GM singularities from the cavity method. The method is exact on Bethe lattices and hence the functional recursion relation to which it gives rise must contain GM physics which exists already on these lattices. The challenge then, is to extract it by constructing the appropriate fixed point solution. To this end we study the particular case of a diluted ferromagnet on the Bethe lattice which has an extended GM region at low temperatures and large dilution. While the general, exact, determination of GM singularities anywhere in the phase diagram is a hard problem, we are able to solve the problem in the infinite coupling limit made precise below. Here we can directly solve the cavity equations in a field and relate the solution to the statistics of clusters and to the density of Lee-Yang zeros commonly used to characterize GM effects. Further, in this limit the phase transition between the paramagnet and the ferromagnet is itself essentially of a GM character and its critical behavior, which we extract, can be viewed as an enhanced GM phenomenon.

The problem of the dilute Bethe lattice ferromagnet and of GM singularities has been considered before us [10, 11] by different methods. As our interest is primarily in the development of the cavity method, we give a self-contained presentation in this paper from that viewpoint. We turn now to a more detailed enumeration of the contents of this paper.

II. MODEL AND ORGANIZATION

We consider the following disordered Ising Hamiltonian on the Bethe lattice with connectivity q:

$$\beta H = -J \sum_{\langle ij \rangle} \epsilon_{ij} \sigma_i \sigma_j - H \sum_i \sigma_i,$$

(1)

where $$\epsilon_{ij} = \begin{cases} 1 & \text{with probability } p; \\ 0 & \text{with probability } 1 - p. \end{cases}$$

The random couplings $$\epsilon_{ij}$$ indicate the presence or absence of a bond in the diluted Bethe lattice. For probability $$p < p_c = 1/(q-1)$$ the lattice has no giant clusters and the density of large finite clusters decays exponentially. For $$p > p_c$$, giant clusters exist with finite density and at the percolation transition, $$p = p_c$$, the density of clusters of size n develops a long algebraic tail $$W_n \sim n^{-5/2}$$ (independent of q) [12]. We note that the dimensionless coupling constants J and H differ from the conventional magnetic exchange and field by factors of inverse temperature $$\beta = 1/T$$. The limit $$T \to 0$$ with $$J \gg H$$ will be denoted as the $$J = \infty$$ limit.

In Section [11] we provide a guided tour of the well-known phase diagram of this model from the point of
view of the cavity method. We then establish the critical behavior at the phase transitions using a set of recursion relations for the moments of the cavity field distribution. We also show that the critical behavior can be extracted via a simple numerical algorithm, which we discuss in some detail in the Appendix.

The following sections are devoted to investigating exact analytic results in the infinite (dimensionless) spin-spin coupling limit, $J = \infty$. This corresponds to the horizontal axis of the phase diagram in Figure I. In Section IV we find an explicit expression for the magnetization $M(H)$ by means of a sum over connected clusters, which follows the standard GM treatment due to [13]. In Section V we show that the same expression can, in fact, be extracted from the cavity method. In this limit, the magnetization goes to zero with the field for $p \leq p_c = 1/(q-1)$ while for $p > p_c$, a spontaneous magnetization develops. We first show that: 1) for $p < p_c$ the asymptotic series expansion for the magnetization contains only integer powers $M(H) = \chi H + c_3 H^3 + \ldots$ and 2) on the contrary at $p = p_c$, the series expansion contains semi-integer powers as well $M(H) = c_{1/2} \sqrt{H} + c_1 H + c_{3/2} H^{3/2} + \ldots$. That is, the critical exponent $\delta = 2$ at $p = p_c, J = \infty$.

In Section VI we develop an alternative integral representation for $M(H)$ that corresponds to a harmonic expansion. This representation will allow us to calculate the (smoothed) density of Lee-Yang (LY) zeros $\rho_{sm}$ at $J = \infty$ on the imaginary $H$ axis ($\theta = \text{Im} H$) in Section VII and to show that for $p < p_c$ a GM phenomenon indeed occurs, i.e. the density of zeros is non-zero and vanishes as $e^{-\alpha/\theta}$ when approaching the origin. For $p = p_c$ we find $\alpha = 0$ and the density vanishes as the power law $\rho \propto \sqrt{\theta}$.

Finally, the promised Appendix briefly describes the “population dynamics” algorithm used in the numerical work.

III. PHASE DIAGRAM AND CAVITY EQUATIONS

The $p$–$J$ phase diagram (Figure I) of the diluted ferromagnet $\mathcal{H}_e$ is physically well understood and can be derived naturally in a cavity method formalism [14, 15]. In this approach, one considers the flow of cavity fields from the boundaries of the tree inward toward the center. A cavity field $h_i$ on a spin $\sigma_i$ at a distance $d$ from the boundary describes the spin’s magnetization in the absence of the link connecting it to the next spin inward. The cavity field $h_i$ only depends on the cavity fields on $\sigma_i$’s neighbors at distance $d-1$ and therefore one can define a natural flow for the depth dependent distribution of fields $P^{(d)}(h)$:

$$P^{(d)}(h) = \mathbb{E}_e \int \left( \prod_{i=1}^{q-1} dh_i P^{(d-1)}(h_i) \right) \delta \left( h - \sum_{i=1}^{q-1} u(h_i + H, J\epsilon_i) \right)$$

where

$$u(h_i + H, J\epsilon_i) = \tanh^{-1}(\tanh(J\epsilon_i) \tanh(h_i + H))$$

Equation (2) reduces to a flow equation for $h^{(d)}$:

$$h^{(d)} = \sum_{i=1}^{q-1} u(h^{(d-1)} + H, J)$$

$$= (q-1) \tan^{-1} \left( \tanh(J) \tanh(h^{(d-1)} + H) \right)$$

For $J < J_G = \tan^{-1} \left( \frac{1}{q-1} \right)$, the flow at $H = 0$ has only one fixed point $h^{(\infty)} = 0$ corresponding to the paramagnetic phase. For $J > J_G$, the $h^{(\infty)} = 0$ fixed point becomes unstable to a spontaneously magnetized ferromagnetic fixed point with $h^{(\infty)} > 0$. Expansion of the fixed point equation to leading order in $H$ and $\epsilon = (J - J_G)$ gives the well-known mean-field critical exponents at $J = J_G$:

$$M(H, J = J_G) \sim H^{1/\delta}; \quad \delta = 3$$

$$M(H = 0, J > J_G) \sim (J - J_G)^{\beta}; \quad \beta = 1/2$$

In the undiluted model, $p = 1$, all of this discussion reduces to the simple Bethe-Peierls mean field theory for a connectivity $q$ lattice. Since there is no randomness, the cavity field distributions $P^{(d)}$ are simply delta functions located at, possibly depth dependent, fields $h^{(d)}$. 

In Section VII we show that the same expression can, in fact, be extracted from the cavity method.
FIG. 1: Phase diagram for the diluted ferromagnet on the connectivity \( q = 3 \) Bethe lattice.

Under dilution, we must return to the more general cavity distribution flow defined by equation (2) to extract the phase behavior. Notice that the paramagnetic cavity distribution \( P_{PM}(h) = \delta(h) \) is always a fixed point of the flow at \( H = 0 \), just like \( h^{(d)} = 0 \) is always a solution for the undiluted model. As in undiluted case, this fixed point will become unstable above some critical coupling \( J_c(p) \). Near \( P_{PM}(h) \) (i.e. for small \( h \)), we consider the linear stability of the first moment of \( P^{(d)}(h) \):

\[
\langle h \rangle^{(d)} = E_c \int dh \left( \prod_{i=1}^{q-1} dh_i P^{(d-1)}(h_i) \right) \delta \left( h - \sum_{i=1}^{q-1} u_i \right) \frac{h}{h_{c}} \\
= E_c \int \left( \prod_{i=1}^{q-1} dh_i P^{(d-1)}(h_i) \right) \sum_{i=1}^{q-1} u(h_i, J_\epsilon) \\
\approx (q - 1) \langle E_c \operatorname{tanh}(J_\epsilon) \rangle \langle h \rangle^{(d-1)}
\]
to leading order. Thus, \( 1 = (q - 1)p \operatorname{tanh}(J_c(p)) \) gives the critical boundary separating a stable paramagnetic phase from the ferromagnetic phase. A small rearrangement gives:

\[
J_c(p) = \operatorname{tanh}^{-1} \left( \frac{p_c}{p} \right)
\]

This agrees precisely with the undiluted critical point \( J_c(\bar{p} = 1) = J_G \) found above and also predicts that for \( \bar{p} < p_c \) the paramagnetic phase persists for all finite \( J \). There is no ferromagnetic phase transition for a model with only finite clusters, as one expects.

In order to extract the critical behavior along the diluted phase boundary, we wish to expand the fixed point equations near the critical solution as we did in the discussion of the undiluted model. Rather than working with equation (2) directly, it is more natural to use an equivalent infinite set of recursion relations for the moments of \( P(h) \). These can be derived by multiplying both sides of equation (2) by \( h^n \) and integrating or by considering the relation on random variables

\[
h^{(d)} = \sum_{i=1}^{q-1} \epsilon_i \tanh^{-1} \left( \tanh(J \tanh(h_i^{(d-1)}) \right)
\]
taken to the power \( n \) and averaged. Near \( P_{PM}(h) \), we expand this relation around small \( h_i \):

\[
h' = \sum_{i=1}^{q-1} \epsilon_i T(h_i - \frac{1}{3}(1 - T^2)h_i^3) + ...
\]

where \( T = \tanh J \) and we have suppressed the depth superscripts.

Sufficiently near the phase boundary, we expect the moments \( \langle h^n \rangle \) to decrease exponentially with \( n \) and thus only a few leading order moments need be retained to extract the leading critical behavior at finite \( J \). Taking powers of equation (7) and averaging, we find

\[
\langle h' \rangle = 2pT \langle h \rangle - \frac{2}{3}pT(1 - T^2) \langle h^3 \rangle \\
\langle h'^2 \rangle = 2pT^2 \langle h^2 \rangle + 2p^2T^2 \langle h \rangle^2 \\
\langle h'^3 \rangle = 2pT^3 \langle h^3 \rangle + 6p^2T^3 \langle h \rangle \langle h^2 \rangle
\]
to cubic order. We have specialized to the case \( q = 3 \) in order to simplify the presentation; for \( q > 3 \) an additional term at cubic order is generated but the critical exponents remain the same.

Near the phase boundary in the \( p-J \) plane, we can define a small parameter \( \epsilon \) by writing \( 2pT = \frac{p}{p_c} \tanh J = 1 + \epsilon \). We will treat the fixed point equations to leading order in the \( \epsilon \) expansion. For \( \epsilon < 0 \) the only real solution is paramagnetic:

\[
\langle h \rangle = \langle h^2 \rangle = \langle h^3 \rangle = 0.
\]

This solution is stable since its local Lyapunov exponents \( \epsilon, \epsilon - \ln \frac{T}{2}, \epsilon - 2 \ln \frac{1}{2} \) are all negative.

For \( \epsilon > 0 \) this solution becomes unstable. We find two other ferromagnetically ordered solutions, which are linked by the symmetry \( h \rightarrow -h \), and choose the positive one. This is

\[
\langle h \rangle = 2\sqrt{\frac{1 - T}{T}} \epsilon^{1/2} + ...
\]

\[
\langle h^2 \rangle = \frac{2}{T} \epsilon + ...
\]

\[
\langle h^3 \rangle = \frac{6}{\sqrt{T(1 - T)}} \epsilon^{3/2} + ...
\]

One can find the Lyapunov exponents of this stationary point analytically but the expressions are unenlightening. We plot a typical case in Figure 2. Notice that the results (9) are consistent with the assumption that \( \langle h^n \rangle \) decreases exponentially with \( n \).

From Eq. (9) one can read off the critical exponent \( \beta = 1/2 \) as the power of \( \epsilon \) in \( \langle h \rangle \sim m \). This is valid for all...
$T < 1$ and sufficiently small $\epsilon$. The point $T = 1$ ($J = \infty$) is different and needs to be treated more carefully. As $T \to 1$ the coefficient of $\epsilon^{3/2}$ in (9) vanishes, which implies that the $J = \infty$ critical exponent $\beta' > 1/2$ while the divergence of the coefficient of $\epsilon^{3/2}$ means that $\beta' < 3/2$. Indeed, from the exact solution of Section IV we will find $\beta' = 1$.

For sufficiently large $\epsilon > \epsilon_c$, the Lyapunov exponents become positive, signaling a loss of stability of the third order ferromagnetic solution (for the value $J = 1$, $T = \tanh(1)$ in Figure 2, $\epsilon_c = 0.137...$). This indicates that the first few moments flow to large scale and our truncation to cubic order fails. The value of $\epsilon_c$ decreases monotonically as $T$ approaches 1 and to accurately find the fixed points we need to keep track of more moments of $\epsilon$ in our iteration equations. At this point it is convenient to switch to numerical solution of the full cavity equation (2) by population dynamics, as described in the Appendix.

Having explored both above and below the critical point, we return briefly to the critical point at $\epsilon = 0$. Here, at linear order, there is a marginal flow near the paramagnetic fixed point. It is possible to analyze the truncated flow equations at higher order to discover that the paramagnetic solution is indeed algebraically (rather than exponentially) stable, as one expects of a second order phase transition. With some additional algebra it is possible to carry a small applied field $H$ through all of the above arguments at $\epsilon = 0$ and show that the critical exponent $\delta = 3$ all along the $p > p_c$ phase boundary.

The final important feature of the phase diagram is the presence of GM singularities throughout the $p < 1$, $J > J_G$ region. That is, the density of LY zeros on the imaginary $H$ axis of the partition function has an essential singularity like $e^{-\sigma_i}/\sin H$ throughout this region due to the cumulative influence of rare large undiluted

---

**IV. CLUSTER SERIES AT $J = \infty$**

For the remainder of the paper, we will focus primarily on the $J = \infty$ part of the phase diagram of the model. We first review the classic argument due to Harris [13] based on an expansion over connected clusters. This will lead to an exact series expansion for $M(H)$ that we will independently rederive using the cavity approach in Section IV.

Consider a cluster of $n + 1$ spins connected by $n$ bonds. For $J >> H \sim 1$ (which is the meaning of the $J = \infty$ limit) each connected cluster behaves like a piece of ferromagnet. Indeed, for $H = 0$ there are two degenerate ground states, one with all spins pointing up and one with all spins pointing down. The first excited states are spin flips at energy $\sim J$ above the ground states and their presence is negligible. Turning on a magnetic field $H$ the degeneracy is broken and (if $H$ is positive, say) the state with all spins pointing up is energetically preferred. Therefore the cluster will acquire a small magnetization:

$$M_n(H) = (n + 1) \tanh((n + 1)H). \quad (10)$$

The total magnetization per spin is obtained by summing over all the clusters with their weights $W_n$, corresponding to the number of clusters of size $n$ per spin [19]

$$M(H) = \sum_{n \geq 0} W_n M_n(H). \quad (11)$$

This equation has been studied before and results can be found in [14] for the magnetization, and [10] for the scaling law of the magnetization at the critical point. We will reproduce those results on the magnetization for completeness, but the main focus of this paper will be the density of Lee-Yang zeros and the solution of cavity field equations from which we will recover the known results.

From the solution of the bond percolation problem on the Bethe lattice [12] the number per spin $W_n$ of clusters of bond size $n$ is given by

$$W_n(p) = q \frac{(n + 1)(q - 1)!}{(n + 1)!((q - 2) + q)!} p^n (1 - p)^{n(q - 2) + q}. \quad (12)$$

For simplicity we consider $q = 3$. Then $p_c = 1/2$. We can easily obtain the asymptotic behavior of the magnetization by using the asymptotics of $W_n$ as

$$W_n = \frac{12}{\sqrt{\pi}} (1 - p)^3 \left( \frac{1}{n} \right)^{5/2} e^{-nA(p)} \quad (12)$$
where

$$A(p) = \ln \frac{1}{4p(1-p)}.$$  \hfill (13)

$A(p)$ is the exponent governing the decay rate of the cluster sizes and it will appear often in the remainder of the paper. For $p < p_c = 1/2$, $A > 0$ and $W_n$ decreases exponentially. For $p = p_c = 1/2$, $A = 0$ and we have instead a power-law decay with exponent $5/2$ (the exponent is independent of $q$):

$$W_n = \frac{3}{2\sqrt{\pi}} \left( \frac{1}{n} \right)^{5/2}.$$  \hfill (14)

This change in the asymptotic fall-off of the cluster distribution at criticality is the reason for the change in the response to an applied external field at zero temperature.

Indeed we can easily see how this works. For $A > 0$ and small $H$ we can write an asymptotic expansion:

$$M(H) = \sum_n W_n (n+1) \tanh((n+1)H)$$

$$\simeq H \langle (n+1)^2 \rangle + \mathcal{O}(H^3)$$

$$= H \frac{(1+p)}{1-(q-1)p} + \mathcal{O}(H^3),$$  \hfill (15)

which is linear in $H$. At the percolation threshold, however, $A = 0$ and $\langle n^2 \rangle$ diverges. The expansion of $\tanh$ inside the first sum is unjustified. To find the first term in the asymptotic expansion of $M$ (that we will derive in a formally correct way in Section VI) we use instead [12]:

$$M(H) \simeq \sum_n \frac{3}{2\sqrt{\pi}} \left( \frac{1}{n} \right)^{3/2} \tanh(nH)$$

$$\simeq \frac{3}{2\sqrt{\pi}} \sqrt{H} \int_0^\infty dx \ x^{-3/2} \tanh x + \mathcal{O}(H).$$  \hfill (16)

So the susceptibility diverges although there is no spontaneous magnetization [13]. We now turn to a derivation of the above results from the cavity method.

V. CAVITY APPROACH AT $J = \infty$

The cavity method for this system gives a probability distribution for the cavity fields which satisfies the fixed point equation (cf. Equation (2))

$$P(h) = E_x \int \prod_{i=1}^{q-1} \delta(h_i + H, J \epsilon_i)$$

In the $J \to \infty$ limit, we can linearize the cavity biases $u$:

$$u(h + H, J \epsilon_i) = (h + H) \epsilon_i$$  \hfill (18)

At $q = 3$, the fixed-point equation [17] becomes

$$P(h) = (1 - p)^2 \delta(h) + 2p(1-p)P(h - H)$$

$$+ p^2 \int dh_2 P(h_2 - 2H)P(h - h_2).$$

This equation can be solved by defining the Laplace transform

$$g(s) = \int_0^\infty dhP(h)e^{-sh},$$

making sure to include the delta function at $h = 0$. The equation for $g$ is quadratic

$$0 = p^2 e^{-sH}g(s)^2 + (2p(1-p)e^{-sH} - 1)g(s)$$

$$+ (1-p)^2.$$  \hfill (19)

with solution

$$g(s) = \frac{e^{2Hs} - 2e^{Hs}(p - p^2) - e^{Hs}(p - p^2)^2}{(2p^2)},$$  \hfill (20)

The second solution to (19) is not physical. Even without inverting the Laplace transform all the properties of the solution can be extracted from $g(s)$. For example the normalization condition, the zeroth moment, is

$$\int_0^\infty dhP(h) = g(0) = \begin{cases} 1 & \text{if } p \leq 1/2; \\
\frac{1-p^2}{p^2} & \text{if } p > 1/2. \end{cases}$$

and the first moment is

$$\langle h \rangle = -\frac{\partial g}{\partial s} \bigg|_{s=0} = \frac{2Hp}{1 - 2p}.$$  \hfill (21)

whose divergence at $p = p_c = 1/2$ signals the ferromagnetic phase transition. For $p > p_c$, $P(h)$ loses normalization because a finite fraction of the cavity fields flow to infinity, just as in a percolating cluster distribution. Indeed, the divergent cavity fields are precisely those attached to spins in percolating clusters. Because these spins are connected to the positively biased boundary and the temperature is effectively zero, they spontaneously magnetize to $M = 1 = \tanh(\infty)$. This provides the spontaneous magnetization critical exponent:

$$M(H = 0, J = \infty, p) = 1 - \frac{(1-p)^2}{p^2} \propto (p - p_c)^1,$$

from which we read $\beta' = 1$ in accord with the discussion following Eq. (9).

We now concentrate on the $p \leq p_c = 1/2$ region at finite $H$. Consider the magnetization per spin

$$M(H) = \left( \tanh(H + \sum_{i=1}^{q} u(h_i + H, J \epsilon_i)) \right)_{c,h_i}.$$  \hfill (22)

which is obtained by averaging over the disorder and the distribution of $h$. It is straightforward to show that for
small $h$ and $H$ we obtain the results of Equation (15). Indeed:

$$M(H) = \left( H + \sum_{i=1}^{q} \epsilon_i (h_i + H) \right) e_{h_i,\epsilon} + \mathcal{O}(H^3)$$ \hspace{1cm} (23)

$$= (1 + pq)H + qp \langle h \rangle + \mathcal{O}(H^3)$$ \hspace{1cm} (24)

Now substitute (21) and simplify

$$M(H) = H \frac{(1 + p)}{1 - (g - 1)p} + \mathcal{O}(H^3),$$ \hspace{1cm} (25)

in accordance with (15).

We now reconstruct the full probability distribution $P(h)$ exactly. We expand the function $g(s)$ as a series in $e^{-snH}$

$$g(s) = \sum_{n \geq 0} \alpha_n e^{-snH}$$ \hspace{1cm} (26)

which defines the coefficients $\alpha_n$. $P(h)$ is now given by the inverse Laplace transform,

$$P(h) = \sum_{n \geq 0} \alpha_n \delta(h - nH).$$ \hspace{1cm} (27)

The $\alpha_n$ are given by the series expansion of the square root in (20):

$$\alpha_n = \frac{(4p(1-p))^{n+2}}{2p^2} \frac{(-1)^{n+1} \Gamma(3/2)}{\Gamma(n+3) \Gamma(-n-1/2)},$$ \hspace{1cm} (28)

That is, $P(h)$ is a comb of delta functions at integer multiples of $H$ with a decaying envelope. The large $n$ behavior of the envelope is

$$\alpha_n = \frac{4(1-p)^2}{\sqrt{\pi}} n^{-3/2} e^{-A(p)n} + \ldots,$$ \hspace{1cm} (29)

where $A(p)$ is defined in (13). It is not surprising that the same asymptotics governs both $P(h)$ and $W_n$.

Finally, to connect directly with the previous section let us compute the exact magnetization of a spin as a function of applied field $H$. Evaluating the cavity magnetization equation (22) using the cavity field distribution (27), we find

$$M(H) = \sum_{j=0}^{q} \left( \frac{q}{j} p^j (1-p)^{q-j} \right) \sum_{m_1, \ldots, m_j=0}^{\infty} \alpha_{m_1} \cdots \alpha_{m_j} \tanh ((j + 1 + m_1 + \cdots + m_j)H)$$ \hspace{1cm} (30)

Laplace transform of the function $\tanh x$

$$f(s) = \int_0^\infty dx e^{-sx} \tanh x$$

$$= \frac{1}{2} \left(-\frac{2}{s} - \psi \left( \frac{s}{4} \right) + \psi \left( \frac{2 + s}{4} \right) \right),$$ \hspace{1cm} (31)

where $\psi$ is the digamma function. The function $f(s)$ has simples poles only at the negative even integers and thus we can invert the transform and write

$$\tanh x = \int_B^\infty \frac{ds}{2\pi i} e^{sx} f(s),$$ \hspace{1cm} (32)

where $B$ is any Bromwich path lying to the right of all poles of $f(s)$, that is to the right of the negative real axis. Inserting into (11), we can invert sum and integral, provided

$$|4p(1-p)e^{sH}| < 1.$$ \hspace{1cm} (33)

The resulting expression, valid for $|\arg H| < \pi/2$,

$$M(H) = 3(1-p)^3 \int_B^\infty \frac{ds}{2\pi i} f(s)$$

$$\times \sum_{n \geq 0} \frac{2(n+1)!}{(n+3)!n!} e^{s(n+1)H} (p(1-p))^n$$

VI. AN INTEGRAL REPRESENTATION FOR THE MAGNETIZATION

Despite its simplicity, the expansion of Eq. (11) is an exact result for the magnetization which can be analytically continued to imaginary values of the magnetic field. However, the representation of $M(H)$ as a sum in (11) is not best suited for this purpose. An integral representation would be preferable. To obtain it we write the
can be written in closed form by performing the sum. This amounts to calculating the derivative of the generating function of the probability $W_n$. For the Bethe lattice the generating function is $20$

\[ \phi(x) = \sum_{n \geq 0} W_n x^n = -2(1-p)^3 x^{-3} (8(1-\sqrt{1-\xi}) + 4(2\sqrt{1-\xi-3}\xi + 3\xi^2)) \] (34)

where $\xi = 4p(1-p)x$ has been defined for convenience. By means of this function we can perform the sum inside the integral to obtain

\[ M(H) = \frac{3(1-p)^3}{6p^3(1-p)^3} \int_{B} \frac{ds}{2\pi i} f(s)e^{-2sH} \times \left( (p(1-p)e^{sH} - 1) \sqrt{1 - 4p(1-p)e^{sH} + 1 - 3p(1-p)e^{sH}} \right). \] (35)

We simplify this expression by considering the analytic structure of the integrand. The function $f(s)$ has simple poles only at the negative even integers (0, -2, -4, ...), while the rational expression has a series of square root cuts at $s = \pm \frac{\pi}{H}$. We close the contour with a semicircle at infinity on the right (for $\text{Re} s > 0$) on the first Riemann sheet. We then deform the contour to coincide with the edges of the cuts. At this point only the discontinuity across the cuts contributes to the final result. For aesthetic reasons we finally shift the value of $s$ by $\frac{A(p)}{H}$, the real part of the origins of the cuts.

The resulting expression is

\[ M(H) = \sum_{n=-\infty}^{\infty} \frac{8(1-p)^2}{\pi p} \int_{0}^{\infty} ds \left( 1 - \frac{1}{4}e^{sH} \right) \sqrt{e^{sH} - 1} f(s + s_n^*) e^{-2sH}. \] (36)

At this point it seems we have traded a sum of functions $16$ with a series of integrals that we cannot evaluate. This looks like a step backward in the quest for a useful result! However, after thinking about the procedure we have performed, we recognize that this is a Poisson summation-like duality on the original equation $11$. The terms in the sum are higher and higher harmonics of the result (this is particularly evident, as we will see shortly, for imaginary $H$).

The series in $n$ in (36) is dual to the series in $11$ so that when the first converges rapidly the second does not and vice versa (for $H$ on the real axis). In the interesting regime, close to the percolation threshold $11$ converges slowly and the first term $(n = 0)$ of $36$ gives the leading term in the expansion in $(p - p_c)$ and $H \to 0$.

Let us now see how we can recover Eq. $16$ in a clear way. At the critical point $p = 1/2$, we have $A = 0$ and so $s_n^* = i2\pi n/H$. For $H \to 0$ all the cuts except that corresponding to $n = 0$ go to infinity and we can keep only the $n = 0$ term in the series $36$. Moreover, by expanding the integrand in powers of $H$ we find

\[ M(H) \simeq \frac{3}{\pi} \sqrt{H} \int_{0}^{\infty} \sqrt{s} f(s) + O(H) \]
\[ = \frac{3}{\pi} \sqrt{H} \frac{\sqrt{\pi}}{2} \int_{0}^{\infty} x^{-3/2} \tanh x + O(H) \]

which coincides with Eq. $16$.

To recapitulate, the magnetization is given by an integral of the discontinuous part of the generating function $\phi$ of the cluster distribution $W_n$ with the Laplace transform of the function $\tanh x$. For the Bethe lattice the generating function can be written down explicitly and the calculations can be carried to the end. In the percolation limit the cut on the real axis gives the greatest contribution to the sum.

VII. DENSITY OF LEE-YANG ZEROS AT $J = \infty$

In this Section we will find the density of Lee-Yang zeros $\rho$ at $J = \infty$. These are the zeros of the partition
FIG. 3: The density of Lee-Yang zeros as a function of the imaginary field $\theta$ at $p = 1/4$. In red the smoothed $\rho_{\text{sm}}$, in orange the sum of the first three harmonics in (36) (terms $n = \pm 1, \pm 2, \pm 3$) and in blue $-\rho_{\text{sm}}$. The figure suggests (in agreement with the discussion in the text) that the sum of all the harmonics (with $n \neq 0$) builds a sum of delta functions in $\rho(\theta)$ in (40).

The density as a function of the external magnetic field $H$, for imaginary $H = i\theta$. Instead of solving the equation $Z(H) = 0$ directly, we rely on the relation

$$
\rho(\theta) = \frac{1}{\pi} \text{Re} M(i\theta + 0^+).
$$

To get an idea of how this function looks we recall

$$
\text{Re} \tanh(i\theta + 0^+) = \pi \sum_{m=-\infty}^{\infty} \delta(\theta - \frac{\pi}{2}(2m + 1)).
$$

From this we find

$$
\rho(\theta) = \sum_{m} \sum_{n \geq 0} W_n(n+1) \delta((n+1)\theta - \frac{\pi}{2}(2m+1)) = \sum_{m,n} W_n \delta \left( \theta - \frac{2m+1}{2n+2} \right),
$$

so the zeros are located at all the odd rational multiples of $\pi$, with multiplicities given by the $W_n$'s [21]. This is a singular distribution with an accumulation point at $\theta = 0$: our task is now to smooth it by using the Poisson-dual integral representation (36) obtained in the previous section.

The expansion over the cuts, for imaginary $H$ becomes an expansion in higher and higher harmonics (see Figure 3) of $\rho$. Selecting the term with $n = 0$ in (36), gives the function smoothed to the lowest degree:

$$
\rho_{\text{sm}}(\theta) = \frac{8(1-p)^2}{\pi^2 p} \int_0^\infty ds \sqrt{e^{4s\theta} - 1} \left( 1 - \frac{\pi}{4} e^{s\theta} \right) e^{-2s\theta} \text{Im} f(-is - iA/\theta + 0^+).
$$

This expression simplifies since from the definition of $f$

$$
\text{Im} f(-iz + 0^+) = \int_0^\infty dx \sin(zx) \tanh x = \frac{\pi}{2 \sinh \pi z/2}.
$$

So we find the smoothed density of LY zeros

$$
\rho_{\text{sm}}(\theta) = \frac{4(1-p)^2}{\pi p} \int_0^\infty ds \sqrt{e^{4s\theta} - 1} \left( 1 - \frac{\pi}{4} e^{s\theta} \right) \frac{e^{-2s\theta}}{\sinh \left( \frac{\pi}{2} (s + A/\theta) \right)}.
$$

The different profiles for this density can be seen in Figure 4. Here the GM phenomenon is evident: even at $p < p_c = 1/2$, $\rho_{\text{sm}}(\theta)$ is strictly positive for any non-zero $\theta$; there is no gap in the distribution. This effect is due to the presence of rare large clusters. The asymptotic expansion of the density at small $\theta$ can be found by expanding the integrand

$$
\rho(\theta) \simeq \frac{3\sqrt{2}(1-p)^2}{4\pi^2 p} \sqrt{e} e^{-A/\theta}.
$$

This expansion is uniformly valid at the point $A = 0$, which is $p = p_c$, where it shows the critical square root cusp in the magnetization. However, let us remark that Eq. (40) is the smoothed part (in the sense of distributions) for all values of $\theta$ and not only for small $\theta$.

Let us now make a few qualitative remarks on the asymptotic expansions for $M(H)$ and $\rho$ which apply in principle to all lattices. From the integral representation we observe that there is no Stokes phenomenon for
Re $H > 0$, i.e. the asymptotic approximation for $M(H)$,

$$M_L(H) = \sum_{k=0}^{L} a_k H^{2k+1} \langle (n+1)^{2k+2} \rangle + O(H^{2L+1}) \quad (42)$$

(where $a_k$’s are the coefficients in the series expansion for $\tanh x$) is valid for all $|\arg H| < \pi/2$. Naively, substituting $H = i \theta + 0^+$ into this expansion, we obtain a purely imaginary result for any $L$ and we might speculate that $\rho = 0$. However, the expansion (42) is only asymptotic, since $\langle (n+1)^k \rangle \sim k! e^{-kA}$. This means that we cannot take $L \to \infty$ but rather truncate the series at the $L \sim H/A$ where the remainder is smallest. The remainder is never actually zero but it is exponentially small in $1/|H|$. A good quantitative approximation can be found by using the “terminant” [17] of the asymptotic expansion. The terminant is indeed $\infty \cdot e^{-\frac{\pi}{2} A/|H|}$ and it is not purely imaginary for $H = i \theta + 0^+$. Thus, as a general rule we expect the real part of the terminant of the asymptotic expansion of $M(H)$ represents the density of LY zeros in the subcritical region.

VIII. SUMMARY

The diluted Ising ferromagnet on a Bethe lattice is a tractable model that beautifully illustrates many of the key physical features of short-ranged disordered systems. In this paper, we have attempted to present a unified analysis of the model in the framework of the cavity method, from which we derive both well-known elementary results about its phases and non-trivial features such as GM singularities and the infinite coupling critical exponents.

In particular, the ferromagnetic phase boundary lies in the mean-field universality class ($\delta = 3$) at any dilution above the percolation threshold. At this threshold however, the ferromagnetic critical coupling diverges ($J \to \infty$) and our closed form solutions for the cavity distributions in this limit reveal that the critical behavior is governed by the percolation of the underlying lattice ($\delta = 2$). Linear stability analysis of the flow of the cavity moments near criticality naturally reveals the Lyapunov exponents and the associated correlation depth of the stable phases.

Furthermore, at infinite coupling we have explicitly exhibited the essential Griffiths-McCoy singularities in the magnetization for all $p < p_c$, where there is no spontaneous magnetization. By an harmonic resummation of the exact magnetization, we found the smoothed density of LY zeros exactly and conjectured its relation to the real part of an appropriate terminant of the asymptotic series for the magnetization.

APPENDIX: NUMERICAL METHODS

In the cavity framework, all of the statistical observables of a model can be derived from the cavity field distribution $P(h)$. This distribution is the fixed point of the flow of the cavity equation (2). While we can solve this equation analytically in certain limits, we rely on a simple iterative numerical algorithm called population dynamics for many of the finite coupling results. Population dynamics and its more sophisticated variants appear in, for example, [18].

FIG. 4: The density of Lee-Yang zeros as a function of the imaginary field $\theta$ at $p = 1/10$ (above) and at criticality $p = 1/2$ (below).
The algorithm works as follows: we represent the distribution $P(h)$ by a finite population of $N_{\text{pop}}$ fields $h_i$. This population is initialized from an appropriate uniform distribution and then iterated as follows:

1. Select $q-1$ fields $h_i$ randomly from the population and $q-1$ random $\epsilon_{i0}$.

2. Use (2) to calculate the cavity field $h_0$ on a spin sitting below the $q-1$ spins selected above.

3. Randomly replace one element of the population with $h_0$.

4. Repeat until convergence in some measure of the population, for example the cavity magnetization $\langle \tanh(h) \rangle$.

In practice, this procedure converges quickly deep in either the ferromagnetic or paramagnetic phase but slows near the phase transition. We illustrate some typical results below for $q=3$.

Even at the percolating critical point, when the expected cavity distribution develops a long tail and divergent moments, this procedure works. Figure 5 shows the numerically determined cavity field distribution for the $p = 0.5, J = \infty$ critical point with applied field $H = 1$. As noted in Section V the exact solution is a comb of delta functions at $h = nH, n \in \mathbb{N}$ with weights decaying asymptotically as a power law $\alpha_n \sim n^{-3/2}$. The numerical solution concentrates on integer fields with a power-law tail consistent with the exponent $-1.5$.

In general, the form of the cavity field distribution at finite $p$ and $J$ is only obtainable numerically. Figure 6 shows the numerically determined distribution at small applied field $H$ on three different points in the $p-J$ plane near the $p = 0.75, J = 0.80$ critical point. These distributions are typical and illustrate the dramatic increase in susceptibility on the ferromagnetic side of the phase boundary.

Finally, Figure 7 confirms numerically the critical exponents derived using the moment flow analysis of Section III and the exact solution of Section IV.

[19] Notice that in this approach the infinite coupling limit is solvable because the magnetization of a cluster depends only on the number of spins in the cluster and not on its detailed shape.

[20] The generating function can be derived for $q = 4$ as well while for generic $q$ the result is written in terms of hypergeometric functions for which no explicit rational form seems to exist. We see below that the fundamental property of this generating function is to have a square-root branch cut at $\xi = 1$. This exists for all $q > 2$ due to a well-known property of the generalized hypergeometric functions.

[21] Usually, disorder averaging generates a smooth density of LY zeros but not so in the infinite coupling limit of the diluted ferromagnet. This is because the thermodynamics only depend on the size of clusters and not their shape and each cluster of size $n$ contributes zeros precisely at odd multiples of $\pi/2n$.
