Abstract

The existence of bubble nuclei identified by the central depletion in nucleonic density is studied for the conventional magic N (Z) = 8, 20, 28, 40, 50, 82, 126 isotopes (isotopes) and recently speculated magic N = 164, 184, 228 superheavy isotopes. Many new bubble nuclei are predicted in all regions. Study of density profiles, form factor, single particle levels and depletion fraction (DF) across the periodic chart reveals that the central depletion is correlated to shell structure and occurs due to unoccupancy in s-orbit (2s, 3s, 4s) and inversion of (2s, 1d) and (3s, 1h) states in nuclei up to Z \leq 82. Bubble effect in superheavy region is a signature of the interplay between the Coulomb and nn-interaction and depletion fraction (DF) is found to increase with Z (Coulomb repulsion) and decrease with isospin. Our results are consistent with the available data. The occupancy in s-state in \textsuperscript{34}Si increases with temperature which appears to quench the bubble effect.

Keywords: Relativistic mean-field plus BCS approach; Bubble nuclei; Statistical theory for hot nuclei; Magic nuclei; Temperature effect on bubble.
the Fermi energy must be surrounded by orbitals of larger \( l \) (the larger the better) which should be well separated in energy from its nearby single-particle states so that the dynamical correlations are weak. It is important to note that the depletion in the center associated with the vacancy in s-orbit is reinforced by the occupied orbitals whose maximum occurs at the large distances. Hence both the conditions together potentially maximize the bubble effect. Apart from the pairing and dynamical correlations, temperature has been speculated to quench the bubble structure \([19]\) in agreement with one of our results presented in this letter where we have used the statistical theory (ST) of hot nuclei \([20, 21]\) for the first time to investigate the anti bubble effect of temperature. For ground state nuclei (\( T = 0 \)), we use Relativistic mean-field (RMF) plus state dependent Bardeen-Cooper-Schrieffer (BCS) theory \([22, 23]\), which has been generally found to be effective to treat such a wide range of masses that too up to the drip lines \([22–27]\). We perform a systematic study of density profiles, single particle spectra, charge form factor and depletion fraction for the isotonic and isotopic chains of magic nuclei, may not be predominant but may play a subtle role in central depletion of heavier systems.

Recent experimental evidence for bubble in \( ^{34}\text{Si} \) \([2]\) has opened a major frontier for theoretical research, that has, so far, provided a reasonable amount of information \([1–13]\) on potential bubble nuclei such as \( ^{22}\text{O}, ^{34}\text{Si}, ^{46}\text{Ar}, ^{68}\text{Ar}, ^{206}\text{Hg} \), and proton semi-bubble in superheavy \( ^{294}\text{Og} \) \([12]\). The central nucleonic density in superheavy region is entirely driven by the Coulomb repulsion and is related to the symmetry energy \( J \) \([12]\). However, the single-reference (SR) energy density functional (EDF) calculations have been used to study the bubble structure in heavy nuclei. It shows that the ground-state configuration of heavy/superheavy nuclei may display bubble like structure \([28, 29]\), as a result of a collective quantum mechanical effect, sustained by the compromise between the large repulsive Coulomb interaction and the attractive nucleon nucleon strong force. Therefore, it is speculated that the quantum shell effects, which play a major role in bubble effect in lighter nuclei, may not be predominant but may play a subtle role in central depletion of heavier systems.

The inclusion of long range correlations and dynamical quadrupole shape effects have been reported to quench the bubble effect on the basis of MR-EDF \([10, 30]\) and shell-model (SM) \([5]\) calculations, but not eliminate the bubble effect \([13]\). Calculations of \( ^{34}\text{Si} \) \([3]\) with the ab initio many-body method showed that the dynamical correlations reduce the depletion factor by about 0.15 unit without erasing the bubble structure entirely. Furthermore, it is shown \([3]\) that the effect of correlations is not only to change the single-particle occupation probabilities but also the radial shape of the natural wave-functions. This effect becomes less pronounced as \( T \) increases and is expected to completely disappear at a certain critical value of \( T \) around 3–4 MeV which needs further investigation. The tensor-force and the pairing correlations have been found to have important implications in the shell evolution and the bubble structure. The existence of the proton bubble in \( ^{46}\text{Ar} \) shows certain uncertainties. The pairing correlations quench the bubble effect in \( ^{46}\text{Ar} \) whereas the tensor force favors it \([3, 6, 13, 31]\). A better insight on this aspect is expected from the charge density measurements by the upcoming facilities SCRIT, RIBF \([32, 33]\) because \( ^{46}\text{Ar} \), may be, in principle, possible to study with RI production in near future.

To assess the ability of the employed RMF parameter (TMA) to reproduce the experimentally known charge densities, we have compared charge density of magic nuclei \( ^{16}\text{O}, ^{40}\text{Ca}, ^{48}\text{Ca} \) and \( ^{208}\text{Pb} \) with that of the experiments \([34]\) in Fig. 1. Data of experimental \([34]\) density have been extracted from the Fourier-Bessel Coefficients analysis. Fig.
1. shows reasonable agreement in light, medium and heavy mass region. So, we extend our calculations to other nuclei.

The charge densities of $N = 8, 20, 28, 40, 50, 82$ and $126$ isotones plotted in Fig. 2 show the depletion of density at the center ($r = 0$). We find that $^{22}\text{Si}$ ($Z = 14$) in $N = 8$ isotones, $^{30}\text{Ne}, ^{32}\text{Mg}$ and $^{34}\text{Si}$ ($Z = 10, 12$ and $14$) in $N = 20$ isotones show strong bubble structures with the central depletion. The isotones $^{40}\text{Ar}$, $^{50}\text{S}$, $^{58}\text{Ar}$ with $N = 28$ and $40$ and the isotones with $N = 126$ isotones and $Z = 48 – 78$ show up significant central density depletion so are marked as bubble candidates. But isotones with $N = 50$ and $82$ do not show central depression indicating no bubble structure.

So far it is known that the bubble effect relates to the quantum shell effects with its origin in the sequence of occupied and unoccupied s.p. states, in particular, the s-orbital near Fermi level. In view of this, we investigate the occupation probability and s.p. spectra of the proton sd shell ($1d_{5/2}$, $2s_{1/2}$, $1d_{3/2}$) for $N = 8, 20, 28, 40$, and proton $3s_{1/2}$ and $1h_{1/2}$ states for $N = 126$ in Fig. 3. Unoccupancy of $2s_{1/2}$ state in $Z = 8 – 14$ ($N = 8$) isotones (Fig. 3(a)) leads to the central density depletion seen in Fig. 2 (a). In $N = 20$ isotones (Fig. 3(b)), the energy gap between the states ($1d_{5/2}$ and $2s_{1/2}$) increases from $Z = 8$ to $14$ and attains a maximum value of $7\text{MeV}$ at $Z = 14$ with full occupancy in $1d_{5/2}$ state and completely unoccupied $2s_{1/2}$ state that results in the central depletion in $^{34}\text{Si}$ (Fig. 2(b)). Large energy gap at Fermi level marks $^{34}\text{Si}$ a doubly magic nucleus and a prominent proton bubble candidate as expected, in agreement with experimental $^2$ and other theoretical $^3$ works. On the other hand, the energy gap between the states $2s_{1/2}$ and $1d_{3/2}$, decreases from $Z = 8$ to $14$ and attains a small value $\approx 0.2\text{MeV}$ at $Z = 14$. Here both the states being too close to each other get occupied simultaneously following an inversion $^4$ of the states ($2s_{1/2}$ and $1d_{3/2}$). Consequently, $2s_{1/2}$ remains semi-occupied and contributes partially to the depletion of central density in $Z = 16$ and $18$ resulting in the semi-bubble nuclei $^{36}\text{S}$ and $^{38}\text{Ar}$. In $N = 28$ and $40$ isotones (Figs. 3(c), 3(d)), the inversion of $2s_{1/2}$ and $1d_{3/2}$ separated by an energy gap of more than $3\text{MeV}$ results in the fully occupied $1d_{3/2}$ and an unoccupied $2s_{1/2}$ state in $^{40}\text{Ar}, ^{50}\text{Ar}$.
and semi-occupied 2s$_{1/2}$ in $^{56}$S leading to density depletion seen in Fig. 2 ((c) and (d)). Here it may be noted that RMF (with TMA) shows significant central depletion in $^{48}$Ar $^{22}$ due to inversion of 2s$_{1/2}$ and 1d$_{3/2}$ states without including the tensor force $^{11}$. Shell structure of N = 50 and 82 isotopes (Fig. 2 (e), (f)) results in the absence of s$_{1/2}$ state near the Fermi level and shows no bubble character. The inversion of proton states (3s$_{1/2}$ and 1h$_{11/2}$) similar to $^{208}$Hg $^{30}$ results in the unoccupied 3s$_{1/2}$ state in all the N = 126 (Z = 48–78) isotopes indicating bubble structure in the complete chain (seen in Fig. 2(g)).

Fig. 4 shows the neutron density of the isotopic chains $^{12}$–$^{24}$O, $^{34}$–$^{70}$Ca, $^{48}$–$^{98}$Ni, $^{80}$–$^{150}$Zr, $^{98}$–$^{176}$Sn and $^{178}$–$^{262}$Pb as a function of radius where many new neutron bubble nuclei are located.

The occupancy (occ.) of 2s, 3s and 4s states near the Fermi level is shown as a function of neutron number N in the insets of the respective panels of Fig. 4. The zero occupancy of s$_{1/2}$ state in the isotopes of O (N = 8–14), Ca (N = 14), Ni (N = 40–52), Zr (N = 40–60), Sn (N = 48–60) and Pb (N = 126–158) indicate central density depletion which is seen in their respective neutron density plots Fig. 4 ((a)-(f)). Although the Fermi level is far from the unoccupied 3s state in Ni and Zr isotopes but it appears to influence the central depletion. Interestingly, the mirror nuclei (2$^3$O$_{14}$ and 2$^2$Si$_{18}$) and (2$^{34}$Ca$_{14}$, 1$^{34}$Si$_{20}$) (Fig. 4 and Fig. 2) show strong neutron and proton bubbles respectively. $^{80}$Ni$_{52}$, $^{92}$Zr$_{52}$, $^{106}$Sn$_{56}$ and $^{240}$Pb$_{158}$ show significant density depletion. However, the unoccupancy in 2s-state shows stronger density depletion than that in 3s- and 4s-states.

The nuclear charge form factor which is a useful physical observable of central depletion, is a measurable quantity through the elastic electron-nucleus scattering experiments $^{37}$–$^{39}$. Form factor for $^{46}$Ar, $^{34}$Si, $^{48}$Ca and $^{96}$S is displayed in Fig. 5 along with the experimental form factor of $^{48}$Ca $^{34}$ which shows good agreement. Our computed charge density form factor $^{34}$ for bubble and non-bubble nuclei differ in their angular distribution, which may be useful for the future experiments to identify proton bubbles by charge density measurements. Upcoming projects like SCRT $^{32}$ are expected to provide data.

![Figure 5: (Colour online) Nuclear charge form factors with scattering angle for (a) $^{48}$Ca and $^{46}$Ar (b) $^{34}$Si and $^{34}$Ar. Experimental data for $^{48}$Ca extracted from Ref. $^{34}$ is shown.](image-url)
to identify proton bubbles by charge density measurements, are still far from reach as far as our predicted nuclei $^{22}$Si, $^{58}$Ar, $^{56}$S, $^{184}$Ce, $^{34}$Ca, $^{80}$Ni, $^{240}$Pb are concerned. However, our predicted bubble nuclei $^{34}$Si, $^{48}$Ar, $^{22}$O, are in principle possible to do with the slow RI beams for use in SCRIT, which may be produced by a projectile fragmentation reaction of $^{70}$Zn beam, and $^{106}$Sn may be produced from $^{124}$Xe beam. RI beams are slowed down by a gas-catcher system to be used in SCRIT. $^{92}$Zr is easy to do even without SCRIT system which appears to be a potential bubble candidate due to its easy experimental accessibility.

To search for the bubble like structures in superheavy isotones with neutron numbers $N = 164$, 184, 228, which have been recently shown to be magic by us [40] and Refs. [41–43], we use RMF by including deformation with axially deformed shapes [22, 25, 27]. The charge density profiles of $^{251}$Fr, $^{256}$Ru, $^{298}$114, $^{299}$115, $^{301}$117, $^{341}$113 and $^{347}$119 indicate bubble structure with significant central density depletion. The bubble effect and depletion fraction (DF) of $^{251}$Fr, $^{299}$Mc and $^{347}$119 (shown in Fig. 6) are found much stronger as compared to that of $^{302}$Og ($Z = 118$) reported in Ref. [12]. $^{251}$Fr ($Z = 87$, $N = 164$) shows the highest DF that makes it the strongest bubble in the heavy systems seen so far. The depletion fraction (DF) of $N = 164$, 184, 228 isotones shown in Fig. 7(a), (b), (c) increases with $Z$ due to the increasing Coulomb repulsion. But the DF of $Z = 118$, 120 and 122 isotopes (plotted in Fig. 7(d), (e), (f)) decreases as neutron number increases indicating the role of isospin and the interplay between the Coulomb and nn-interaction on the bubble effect.

Keeping $Z$ or Coulomb interaction fixed, variation of DF is related to isospin and is decreasing as a function of $N$ (i.e. asymmetry $(N-Z)/2$ parameter). Although the present study shows the influence of Coulomb and asymmetry energy on bubble effect in superheavy systems but some influence of shell effects may also be present as suggested by Ref. [18] which needs investigation.

In Table I, we show depletion fraction (DF) calculated by using TMA [27], NLSH [44], PK1 [42] and NL3*$^*$ parameters and compare with various other works [6, 4, 11, 13, 16, 12, 35, 31, 47, 48]. Good agreement between our calculated DF and the other theoretical works validates our predicted known bubble candidates as well as the new potential candidates which are expected to be useful and of interest to future theoretical and experimental studies.

Fig. 8 shows the occupation probability ($n_i$) as a function of single particle energies at various temperatures $T = 0.5$–$3.0$ MeV using the Statistical theory of hot nuclei [21, 22] in the most prominent bubble nucleus $^{34}$Si. As $T$ increases, the occupancy ($n_i$) in $2s_{1/2}$ state increases from almost 0 to a much higher value which shows the anti bubble effect of
temperature. Increasing T washes away the shell effects that leads to changes in the deformation and shape towards sphericity with zero deformation at certain critical temperature (T) [20, 49]. However, since the deformation has a quenching effect on the bubble structure, increasing T may have impact on the deformation as well as the bubble structure. The effect of correlations like pairing correlations [10] and shape fluctuations [10] alter the occupancy but cannot sufficiently quench the bubble structure at zero temperature (T = 0). In our preliminary calculations we find that the depletion factor decreases with increasing T and completely vanishes at T = 4 MeV, which is in concise with the recent work [19]. These results along with the detailed study on the impact of temperature on depletion factor would be presented soon in our upcoming work.

To conclude, the bubble structure in isotopic and isotonic chains of the conventional magic proton (neutron) number P (N)= 8, 20, 28, 40, 50, 82 and N=126, and recently speculated magic N = 164, 184, 228 superheavy isotones, is investigated systematically. A complete range of new bubble nuclei is identified in all the mass regions. We employ RMF+BCS approach to study the charge and neutron density profiles, occupation probability and the single particle spectra. This study shows that the central depletion due to unoccupancy in s-orbit is an outcome of shell structure for all the nuclei up to Z = 82. The unoccupied (2s, 3s, 4s) states lead to the proton (neutron) bubble like structure in N (Z) = 8, 20 isotones (isotopes) and neutron bubble in Ni, Zr and Sn and Pb isotopes. The inversion of proton states (2s_{1/2} and 1d_{3/2}) and (3s_{1/2} and 1h_{11/2}) results in proton bubble nuclei in N = 28, 40 and 126 isotones. Many new superheavy bubble nuclei are traced. The depletion fraction (DF) of magic isotones increases with increasing Z (Coulomb repulsion) and that of the superheavy isotopes decreases with increasing isospin which indicates that the bubble effect is driven by the isospin ((N-Z)/2) and the interplay between the Coulomb and nuclear strong forces. DF calculated by various RMF parameters shows consistency with the other works which shows the validity and usefulness of the RMF+BCS approach for describing bubble nuclei over such a wide range of masses. Charge density form factor for bubble and non-bubble nuclei are found to differ in their angular distribution. To identify the proton bubbles by charge density measurements is still out of reach of the current and near future experimental facilities. However, our theoretical conjectures may be useful for future experiments. Temperature induced effects on bubble nuclei are studied using the statistical theory which indicates the anti bubble effect of temperature. But, variation of bubble effect with T needs more rigorous investigation which would be reported in our subsequent works. However, the experimental and other theoretical data for our predicted bubble nuclei are anxiously awaited.
