Abstract

Metastasis is the leading cause of death in cancer patients, and successful colonisation of a secondary organ by circulating tumour cells (CTCs) is the rate-limiting step of this process. We used tail-vein injection of B16-F10 melanoma cells into mice to mimic the presence of CTCs and to allow for the assessment of host (microenvironmental) factors that regulate pulmonary metastatic colonisation. We found that mice deficient for the individual subunits of the NADPH oxidase of myeloid cells, NOX2 (encoded by Cyba, Cybb, Ncf1, Ncf2, and Ncf4), all showed decreased pulmonary metastatic colonisation. To understand the role of NOX2 in controlling tumour cell survival in the pulmonary microenvironment, we focused on Cyba-deficient (Cybatm1a) mice, which showed the most significant decrease in metastatic colonisation. Interestingly, histological assessment of pulmonary metastatic colonisation was not possible in Cybatm1a mice, owing to the presence of large granulomas composed of galectin-3 (Mac-2)-positive macrophages and eosinophilic deposits; granulomas of variable penetrance and severity were also found in Cybatm1a mice that were not injected with melanoma cells, and these contributed to their decreased survival. The decreased pulmonary metastatic colonisation of Cybatm1a mice was not due to any overt defects in vascular permeability, and bone marrow chimaeras confirmed a role for the haematological system in the reduced metastatic colonisation phenotype. Examination of the lymphocyte populations, which are known key regulators of metastatic colonisation, revealed an enhanced proportion of activated T and natural killer cells in the lungs of Cybatm1a mice, relative to controls. The reduced metastatic colonisation, presence of granulomas and altered immune cell populations observed in Cybatm1a lungs were mirrored in Ncf2-deficient (Ncf2tm1a) mice. Thus, we show that NOX2 deficiency results in both granulomas and the accumulation of antitumoural immune cells in the lungs that probably mediate the decreased pulmonary metastatic colonisation.

Introduction

Metastasis is the leading cause of death in cancer patients, and is a multistep process that involves invasion of the basement membrane by the tumour cells, intravasation, survival in the circulation, extravasation, and proliferation at a secondary site [1]. The successful colonisation of a secondary organ by circulating tumour cells (CTCs) is the rate-limiting step in this process [2]. The lung is a common site of metastasis for many tumour types, and is thus a clinically relevant organ for investigation of colonisation factors. Large-scale sequencing has identified genes that are differentially expressed in metastatic cells relative to the primary tumour, and many studies have examined the role of tumour cell intrinsic factors that can regulate metastasis; however, less work has been performed to investigate tumour cell extrinsic factors, i.e., the role of the host, which includes microenvironmental factors such the stroma, endothelial cells, and the immune system.

Tail-vein injection of tumour cells into mice (providing CTCs in the blood) allows for assessment of extrinsic factors that regulate pulmonary metastatic colonisation [3]. As previously published, we used this method to robustly screen 810 genetically modified mouse lines to identify 23 novel microenvironmental (‘tumour cell extrinsic’) regulators of pulmonary metastatic colonisation [4,5], with genes whose loss of function results in...
Materials and methods

Mice

Cyba [Cyba<sup>m1a/EUCOMM</sup>Wtsi] (ES cell clone: EPD0372_5_B08); hereafter referred to as Cyba<sup>m1a</sup> and Ncf2 [Ncf2<sup>m1a/EUCOMM</sup>Wtsi] (ES cell clone: EPD0240_5_B03); hereafter referred to as Ncf2<sup>m1a</sup> mutant alleles were generated by EUCOMM and transmitted through the germline at the Wellcome Sanger Institute (WSI). Mice were genotyped by polymerase chain reaction (PCR) with either a generic strategy to detect the Neo cassette or an allele-specific short-range PCR strategy [16]. The generation, genotyping and characterisation of Cybb (Cybb<sup>jtm11D10mJ</sup>) [17], Ncf1 (Ncf1<sup>jtm1JfJ</sup>) [18] and Ncf4 (p40phox) [19] mutant mice have been previously described. Phenotyping of all mutant mice was performed on homozygotes. The care and use of all mice in this study were in accordance with the UK Animals in Science Regulation Unit’s Code of Practice for the Housing and Care of Animals Bred, Supplied or Used for Scientific Purposes, and the Animals (Scientific Procedures) Act 1986 Amendment Regulations 2012, and all procedures were performed under a UK Home Office Project Licence, which was reviewed and approved by the Sanger Institute’s Animal Welfare and Ethical Review Body. Housing and husbandry conditions of the mice and general experimental design (allocation of mice to a treatment group, blinding, statistical power, etc.) were as detailed previously [4].

Cell lines

The mouse melanoma B16-F10 cell line was purchased from the American Type Culture Collection (CRL-6475), and the metastatic mouse mammary cancer EO771.LMB cell line [20] was a gift from R. L. Anderson (Peter MacCallum Cancer Centre, Australia). The generation of the B16-F10–mCherry cell line has been described previously [4]. All cells were maintained in Dulbecco’s modified Eagle’s medium with 10% (v/v) fetal bovine serum and 2 mM glutamine, and 100 U/ml penicillin/streptomycin (with the addition of 20 mM HEPES for EO771.LMB cells), at 37 °C in 5% CO2 (all tissue culture reagents were from Gibco, Waltham, MA, USA). All cell lines were screened for the presence of mycoplasma and mouse pathogens (at Charles River Laboratories, Wilmington, MA, USA) before being cultured, and were never cultured for more than five passages. None of the cell lines used appear in the International Cell Line Authentication Committee database.

Experimental metastasis assay

B16-F10 (4 × 10<sup>5</sup>) and EO771.LMB (4 × 10<sup>5</sup>) cells resuspended in 0.1 ml of phosphate-buffered saline (PBS) were injected into the tail veins of 6–12-week-old sex-matched syngeneic control and mutant mice. After 10 days, the mice were killed and their lungs were removed, and the metastatic tumour burden was determined either by macroscopic counting (for B16-F10 cells) or mCherry quantitative PCR (qPCR) (for EO771.LMB cells) (as described previously) [3].
Histology and immunohistochemistry

Mouse tissues were rinsed with PBS and then placed in 10% neutral-buffered formalin (NBF) for a minimum of 24 h before being dehydrated and embedded in paraffin; sections were then cut and stained with haematoxylin and eosin (H&E), according to standard histology protocols. Immunohistochemistry was performed after standard antigen retrieval (20 min at 100 °C in citrate buffer, pH 6) and blocking (peroxidase-blocking solution; Dako, Santa Clara, CA, USA) procedures. The primary antibodies used were: rat anti-mouse galectin-3 (Mac-2) antibody (1:1000 dilution; clone M3/38; Cedarlane, Burlington, Ontario, Canada) and rabbit anti-S100β antibody (1:250 dilution; clone EP1576Y; Abcam, Cambridge, UK). The secondary antibodies used were: biotinylated goat anti-rat IgG mouse absorbed antibody and biotinylated goat anti-rabbit IgG antibody (BA-4000 and BA-1000 respectively; both 1:200 dilution; Vector Laboratories, Peterborough, UK), with visualisation being achieved with 3,3′-diaminobenzine and counterstaining with haematoxylin.

Bone marrow chimaeras

Wild-type (F1, CD45.1/2 heterozygous congenic) mice were subjected to 2 × 4.2-Gy whole-body gamma irradiation followed by tail vein administration of 4 × 10⁶ bone marrow cells from either wild-type (CD45.1 congenic) or mutant (Cyba⁺mla or Ncf2⁻²mlc; CD45.2) mice. Six weeks after transplantation, a tail-vein blood sample was taken to assess the relative proportions of CD45.1 and CD45.2 cells (to assess effective reconstitution of the donor bone marrow), and 5 days later an experimental metastasis assay was performed as described above.

Preparation of tissue cell suspensions and flow cytometry

Mice were given a terminal dose of pentobarbitone intraperitoneally before being perfused with 10 ml of PBS by cardiac puncture, and the lungs and spleen were dissected out. To determine the number of melanoma cells present in the lungs, the mice were dosed with 1 × 10⁶ B16-F10–mCherry cells 90 min before perfusion. Preparation of a single-cell suspension for each tissue, enrichment of leukocytes within the cell suspension and staining of the leukocytes with multicolour antibody cocktails and viability dyes was performed as described previously [4]. All samples were analysed on an LSRFortessa SORP instrument (BD Biosciences, Franklin Lakes, NJ, USA) that was calibrated with BD Cytometer Setup and Tracking Beads and software. Compensation was determined with Ultracomp eBeads (eBioscience, San Diego, CA, USA) for all antibodies, and ARC amide-binding beads (Invitrogen, Carlsbad, CA, USA) for live/dead stains. Data acquisition was controlled with BD FACSDiva version 8.0.1 software (BD Biosciences). Data from doublets (determined with FSC-A versus FSC-H gates, and SSC-H versus SSC-W gates), dead cells (determined with the viability dye) and debris (determined with FSC-A versus SSC-A gates) were excluded. A leukocyte gate was set with CD45 and SSC-A, and all cell subsets were reported as the percentage of this parent gate. All samples were analysed with FlowJo X (FlowJo LLC, Ashland, OR, USA).

 Statistical analysis

Data were analysed with GraphPad Prism 6 software (version 6.04) (GraphPad Software, San Diego, CA, USA), and are shown as dot plots with standard error of the mean error bars (or standard deviation error bars for the experimental metastasis assay, for both 90-min and 10-day results). Groups were compared by the use of unpaired, two-tailed Student’s t-tests as appropriate, or two-way ANOVA with Bonferroni’s multiple comparisons correction, as detailed in the figure legends. Survival was calculated with the log-rank (Mantel–Cox) test. Differences between groups were considered to be significant at p ≤ 0.05.

Results

NADPH oxidase-deficient mice show decreased pulmonary metastatic colonisation

The NOX2 complex is composed of two membrane-bound subunits (encoded by Cyba and Cybb) and three cytosolic subunits (encoded by Ncf1, Ncf2, and Ncf4; Figure 1A). Mice deficient (homozygotes) in any of the NOX2 subunits showed a reduced number of metastatic foci in the lungs, underscoring the importance of NOX2 in regulating pulmonary metastatic colonisation (Figure 1B). As the most reduced level of colonisation was seen in Cyba-deficient mice, we decided to focus on the role of Cyba in the pulmonary microenvironment.

Cyba-deficient mice develop pulmonary granulomas

To confirm the macroscopic counts of lungs from B16-F10-dosed mice, lung colonisation was assessed by examination of H&E-stained sections of all five lobes of the lung. However, it was not possible to determine the metastatic burden in the lungs of Cyba⁺mla mice, owing to the presence of very large confluent granulomas, composed of numerous macrophages, including activated and hyperactivated macrophages/histiocytes, as well as some evidence of eosinophilic crystalline debris, in the interstitial stroma of the lung parenchyma (Figure 2A–D). Thus, we used S100 immunohistochemistry to identify the presence of the tumour cells in the lung, histopathological analysis of the lungs was performed on age-matched mice that had not been injected with tumour cells. In contrast to wild-type mice,
Cybatm1a mice showed the presence of granulomas and eosinophilic crystals, with variable degrees of severity and penetrance (Table 1; Figure 2A–D). The granulomas were composed of macrophages, as confirmed by anti-Mac-2 immunohistochemistry (Figure 2E,F).

Concomitant with this, Cyba-deficient mice showed significantly decreased survival as compared with wild-type mice (median survival of 60 weeks and 83 weeks, respectively), due to a combination of increased tumour incidence (Figure 3A) and widespread pulmonary granulomas inducing dyspnoea or respiratory failure. The tumours were primarily lymphomas (Table 2), both in the lungs and in other tissues that were examined (typically the thymus, spleen, liver, kidney, and lymph nodes; Figure 3B,C), with some cases of hepatocellular carcinoma being seen (Figure 3D). Of the 46 Cybatm1a mice that were killed on humane grounds, 38 were killed (82%) because of irregular or laboured breathing, and their lungs showed the presence of granulomas and eosinophilic crystals; three of 46 (6.5%) were graded as mild, and 43 of 46 (93.5%) were graded as moderate–severe (Figure 3E–H). Interestingly, six of 46 (13%) mice did not show any evidence of a tumour (in the lungs or other tissues) at the time of necropsy, but granulomas and eosinophilic crystals were present. Granulomas and eosinophilic crystals were never seen in the lungs of aged wild-type mice.

**Cyba-deficient mice show decreased pulmonary metastatic colonisation**

In order to be able to confirm that the reduced pulmonary metastatic colonisation phenotype we observed was not specific to the B16-F10 melanoma cell line, and to circumvent the need for histological assessment of tumour burden, we used the EO771.LMB breast cancer cell line expressing mCherry [20]. Pulmonary metastatic colonisation in mice that had been given EO771.LMB cells via the tail-vein was assessed by qPCR on DNA extracted from the lungs of the mice (determined by the level of mCherry DNA (present only in the tumour cells) relative to that of vimentin DNA (present in all cells)). As shown in Figure 4A, relative to wild-type controls, Cybatm1a mice showed reduced tumour burden in their lungs 10 days after being tail-vein-dosed with EO771.LMB cells.

Given that ROS can participate in vascular cell function and that Cyba is also expressed in endothelial cells [21], we decided to assess whether the reduced metastatic phenotype was due to an inability of the tumour cells to extravasate from the bloodstream into the lung. As shown in Figure 4B, 90 min after tail-vein administration of F10CS cells (B16-F10 cells expressing mCherry), both wild-type and Cybatm1a mice had similar numbers of F10CS cells present in their lungs, indicating that the reduced pulmonary metastatic colonisation observed in Cybatm1a mice was not due to differences in extravasation from the pulmonary capillaries.

**Role of the immune composition of the lungs**

To determine whether components of the immune system were responsible for the reduced pulmonary metastatic colonisation in Cybatm1a mice, we lethally gamma-irradiated wild-type mice (to ablate their bone marrow stem cells) and tail-vein-administered bone marrow isolated from either wild-type or Cybatm1a mice. After 6 weeks to allow reconstitution of the donor bone marrow, the irradiated recipients were used in an experimental metastasis assay with B16-F10 cells to determine whether this could recapitulate the phenotype seen in Cybatm1a mice. Mice that received Cybatm1a donor bone marrow showed reduced pulmonary metastatic colonisation relative to those that received bone marrow from wild-type mice (Figure 5A). This confirmed that it was a component of the haematopoietic system that was responsible, as least in part, for mediating the reduced pulmonary metastatic colonisation. Interestingly, the lungs of mice that received Cybatm1a donor bone marrow did not show the presence of any granulomas or eosinophilic crystalline deposits (n = 0/8
Figure 2. Granulomas in Cyba-deficient mice. (A) Representative image of a lung from a wild-type mouse showing no granulomas or eosinophilic deposits (magnification: x100). (B) Representative image of a Cyba\textsuperscript{m1a} lung showing a moderate granuloma (magnification: x100). (C) Representative image of a Cyba\textsuperscript{m1a} lung showing extensive severe granuloma formation with scattered lymphoid aggregates (magnification: x50). (D) Representative image of a Cyba\textsuperscript{m1a} lung showing a severe granuloma with the presence of eosinophilic crystalline deposits (magnification: x200). (E and F) Representative images of a wild-type lung (E) and a Cyba\textsuperscript{m1a} lung (F) showing positive immunohistochemical staining for Mac-2 (magnification: x200).

Table 1. Granuloma formation and eosinophilic crystal deposits in the lungs of 6–9-week-old wild-type and Cyba\textsuperscript{m1a} mice

| Genotype      | Absent | Mild | Moderate | Severe | Eosinophilic crystals |
|---------------|--------|------|----------|--------|----------------------|
| Wild-type     | 8/8    | –    | –        | –      | 8/8                  |
| Cyba\textsuperscript{m1a} | 4/8    | 2/8  | 1/8      | 1/8    | 4/8                  |

Lungs from wild-type and Cyba\textsuperscript{m1a} mice at 6–9 weeks of age were collected into 10% NBF and then histologically processed to allow assessment of an H&E-stained slide containing a longitudinal section of all five lobes. The lungs were graded as mild, moderate or severe on the basis of the strongest phenotype seen in at least one of the five lobes. The grading of the severity of the eosinophilic granules present matched that of the granulomas.

Given that the haematopoietic system was implicated in mediating metastatic colonisation, and that lymphocytes are known to kill tumour cells, we collected the lungs of mice that had been perfused with saline to remove blood from the blood vessels, and performed immunophenotyping of the lymphocyte populations present. As shown in Figure 5B, Cyba\textsuperscript{m1a} and wild-type mice showed no differences in the relative percentages of B lymphocytes, T lymphocytes or NK cells in their lungs. However, regarding the T cells present in the lungs, Cyba\textsuperscript{m1a} mice showed a significantly higher proportion than wild-type controls of antitumoural effector memory T cells (CD44\textsuperscript{hi}CD62L\textsuperscript{lo}) that were activated/antigen-experienced (KLRG1\textsuperscript{+}; Figure 5C). Interestingly, this phenotype was not observed in the spleen (data not shown). Similarly, regarding the NK cells present in the lungs, those from Cyba\textsuperscript{m1a} mice were more activated than those from wild-type mice, and this was also observed in the spleen (Figure 5D).
Lung metastatic colonisation and granulomas in NOX2-deficient mice

Figure 3. Aged Cyba-deficient mice. (A) Kaplan–Meier curve showing tumour-free survival of wild-type (blue circles) and Cyba-deficient (red squares) mice. Statistical analysis was performed with a log-rank (Mantel–Cox) test. (B) Representative image of a lymphoma in the lung of a Cybatm1a mouse (magnification: ×100). (C) Representative image of a lymphoma in the liver of a Cybatm1a mouse (magnification: ×100). (D) Representative image of a hepatocellular carcinoma in a Cybatm1a mouse (magnification: ×200). (G) Representative image of a Cybatm1a lung showing a severe granuloma with eosinophilic crystalline deposits. Note the coexisting lymphoma (magnification: ×40). (H) Representative image of a Cybatm1a lung showing eosinophilic crystals and multi-crystal deposits with associated pleural plaque formation (magnification: ×200).

Cyba-deficient mouse pulmonary phenotypes were mirrored in Ncf2-deficient mice

As the p22phox (Cyba) subunit of NOX2 is present in other NOX complexes, specifically NOX1, NOX3, and NOX4, we next investigated whether the pulmonary phenotypes that we observed in Cyba-deficient mice were also present in Ncf2-deficient mice, as the p67phox (Ncf2) subunit is unique to NOX2.

Ncf2-deficient mice showed decreased pulmonary metastatic colonisation by EO771.LMB breast cancer cells relative to wild-type mice (Figure 6A). Similarly, lethally irradiated wild-type mice that received Ncf2tm1a donor bone marrow showed decreased pulmonary metastatic colonisation by B16-F10 melanoma cells relative to those that received donor bone marrow from wild-type mice (Figure 6B). Immunophenotyping of the
and Cybatm1a cohorts. U and statistical analysis was performed with a Mann–Whitney -test. Data are representative of at least three independent experiments.

Table 2. Diagnosis of wild-type and Cyba tm1a ‘tumour watch’ mice

| Genotype       | Lymphoma | Hepatocellular carcinoma | Harderian gland hyperplasia | No tumour | Pulmonary granulomas | Pulmonary eosinophilic crystals |
|----------------|----------|--------------------------|-----------------------------|-----------|----------------------|--------------------------------|
| Wild-Type      | 13/14    | 1/14                     | 2/14                        | 0/14      | 0/14                 | 0/14                           |
| Cyba tm1a      | 39/46    | 1/46                     | 2/46*                       | 0/46      | 46/46                | 46/46                          |

After 85 weeks, 14 of 30 wild-type mice and 46 of 50 homozygous Cyba tm1a mice had been killed on humane grounds and necropsies had been performed for histopathological diagnosis. *One mouse also had a Harderian gland adenoma.

Figure 4. Cyba-deficient mice show decreased pulmonary metastatic colonisation. (A) Experimental metastasis assay using EO771.LMB breast cancer cells administered to wild-type (+/+) and Cyba tm1a mice, in which pulmonary metastatic colonisation was measured by mCherry qPCR and represented as relative lung tumour burden per mouse. (B) Number of F10CS melanoma cells present in the lungs of wild-type (+/+) and Cyba tm1a mice, 90 min after tail-vein administration. Symbols represent individual mice, and statistical analysis was performed with a Mann–Whitney U-test. Data are representative of at least three independent experiments.

Discussion

Decreased pulmonary metastatic colonisation has been previously reported in Cybb-deficient mice [2,22,23]; however, we show here that mice deficient for any of the five subunits of NOX2 (Cybb-deficient, Cyba-deficient, Ncf1-deficient, Ncf2-deficient and Ncf4-deficient mice) have decreased pulmonary metastatic colonisation. To gain mechanistic insights into how loss of NOX2 could be affecting pulmonary colonisation by CTCs, we chose two of these mutant mouse lines for further investigation. We chose the Cyba tm1a and Ncf2 tm1a lines because they: (1) were generated at the WSI (and so were on the same strain/genetic background); (2) represent a transmembrane component versus a cytosolic component of NOX2 (respectively); and (3) represent a component present in other NOX complexes versus one found only in NOX2 (respectively).

Decreased pulmonary metastatic colonisation was seen in irradiated wild-type mice that received Cyba tm1a or Ncf2 tm1a bone marrow (but not wild-type bone marrow), suggesting that this phenotype is primarily mediated by the immune system. Immunophenotyping of the lungs of Cyba tm1a mice showed an increased percentage of activated T effector cells and NK cells. Interestingly, increased levels of activated T cells were seen only in the lungs of the mice, not in their spleens, suggesting that the lungs were providing a microenvironment conducive to the activation of the T cells, as opposed to a systemic increase in the percentage of activated T cells. In contrast, the increase in the percentage of activated NK cells was seen in both lung and spleen. Both T cells and NK cells are known to have strong antitumoural functions, and so could be responsible for mediating the reduced pulmonary metastatic colonisation seen in these mice. Given that Ncf2 tm1a mice showed only a small increase in the percentage of activated T lymphocytes, but showed a significant increase in the percentage of activated NK cells, it is tempting to speculate that...
NK cells are the main mediators of this phenotype. Metastatic colonisation is strongly regulated by NK cells, and in vivo depletion of NK cells in wild-type mice results in significantly increased pulmonary metastatic colonisation [3]. Interestingly, in vivo depletion of NK cells in Cybb-deficient mice was recently shown to result in increased pulmonary metastatic colonisation by B16-F10 cells, with the degree of metastasis more than doubling in NK-cell-depleted Cybb-deficient mice relative to NK-cell-depleted wild-type mice, which the authors suggested implied increased functionality of NK cells in the absence of NOX2 [23]. In vivo depletion of NK cells in both Cyba<sup>+/+</sup> and Ncf2<sup>+/+</sup> mice gave inconsistent results, despite being able to demonstrate the effectiveness of the NK1.1 antibody treatment by confirming loss of NK cells in the blood (data not shown). This variability may be due to only a partially penetrant role for CD8<sup>+</sup> T-cells, or may be due to the granulomas. Granulomas are present in Cyba<sup>+/+</sup> and Ncf2<sup>+/+</sup> mice as early as 6–9 weeks of age with varying penetrance and severity, and these pools of macrophages could release signals that have an effect on the ability of the tumour cells to undergo metastatic colonisation and/or affect the immune cells present in the lung – thus adding a confounding factor to the analysis of Cyba<sup>+/+</sup> and Ncf2<sup>+/+</sup> mice that would not exist in wild-type mice. We noted that the granulomas were frequently macroscopically obvious in NK cell-depleted Cyba<sup>+/+</sup> mice, and histological analysis confirmed that NK cell depletion resulted in both increased presence and increased size of granulomas in Cyba<sup>+/+</sup> mice (data not shown), suggesting that the NK cell depletion enhanced granuloma formation; also, NK cell depletion has been reported to cause an increase in granuloma diameter in several mouse models of granulomatous inflammation, without any effect on T-cell subsets or proliferative ability [24].

The stronger metastatic colonisation and protumoural immune cell population phenotype seen in Cyba<sup>+/+</sup> mice relative to Ncf2<sup>+/+</sup> mice may be due to the fact that...
Figure 6. The pulmonary metastatic colonisation, lymphocyte populations and granulomas in Ncf2-deficient mice. (A) Experimental metastasis assay using EO771.LMB breast cancer cells administered to wild-type (+/+ ) and Ncf2\textsuperscript{tm1a} mice, in which pulmonary metastatic colonisation was measured by mCherry qPCR and represented as relative lung tumour burden per mouse. (F) The same Ncf2\textsuperscript{tm1a} lung showing positive immunohistochemical staining for Mac-2 (magnification: \times200). (G) Representative image of an Ncf2\textsuperscript{tm1a} lung showing severe granuloma formation and eosinophilic crystals (magnification: \times200). Symbols represent individual mice; the horizontal bar indicates the mean. \( P \) values were obtained with Mann–Whitney \( U \)-tests, and the data are representative of two independent experiments (A and B), or \( P \) values were obtained with two-tailed unpaired \( t \)-tests adjusted by use of the Holm–Šídák method with \( \alpha \) set to 5%, and the data are representative of two independent experiments (C and D). NS, not significant; Teff, effector T cell; Treg, regulatory T cell.
The Cyba subunit is present in other NOX complexes, specifically NOX1, NOX3, and NOX4. For example, unlike Ncf2-deficient mice, Cyba-deficient mice have a balance disorder (see the IMPC website: http://www.mousephenotype.org/data/genes/MGI:1316658#section-associations and [25]) caused by the aberrant development of the gravity-sensing organs, as NOX3 is primarily expressed in the inner-ear epithelium [25]. Cyba-deficient mice (nmf33 mice) have been shown to develop a CGD-like immune defect, as the inability of the phagocytes to produce bacteria-destroying ROS means that these mice have increased susceptibility to bacterial infections, dying a few days after intratracheal inoculation of Burkholderia cepacia; their lung tissue was greatly damaged by necrotising pneumonia, and the alveolar spaces were filled with neutrophil granulocytes, macrophages, and cell debris, in contrast to only minimal granulocytic infiltration into the peribronchial and perivascular areas in lungs from wild-type mice [25]). In agreement with this, Cyba<sup>mla</sup> mice have been shown to die a few days after intravenous administration of Salmonella enterica serovar Typhimurium [26]. However, this is the first report of the presence of macrophage infiltration in the lungs resulting in the formation of granulomas with eosinophilic crystalline deposits in Cyba-deficient (and Ncf2-deficient) mice that have not been deliberately exposed to a microorganism and that were housed in a specific pathogen-free (SPF) environment. Histopathological analysis of the lungs from 6–9-week-old Cyba<sup>mla</sup> and Ncf2<sup>mla</sup> mice showed granulomas and eosinophilic crystals, with variable degrees of severity and penetrance, that were absent from the lungs from age-matched wild-type mice (Table 1; Figure 3A–D). The grading of the lung granulomas and eosinophilic crystals usually went together (i.e. mild granulomas with mild crystals, moderate with moderate, etc.), which suggests that the crystal generation and granuloma formation form part of the same or closely related inflammatory processes in the lung. Previously, Ym1/2 neutrophilic granule proteins have been shown to form eosinophilic crystals in an Ncf1-deficient CGD mouse model, and this was suggested to be due to excess neutrophilic turnover at inflammatory foci [27]. The variability in the presence and severity of the granulomas (and crystals) may relate to the age of the mice, presumably because the inability to produce ROS makes the mouse susceptible, but granuloma formation is triggered by environmental events/exposure such as low-level lung infection that are variable and less predictable.

Interestingly, despite the mice living in the same SPF conditions, the granulomas progressed at a higher rate in Cyba<sup>mla</sup> mice than in Ncf2<sup>mla</sup> mice, as the majority had to be humanely killed because of difficulty with breathing, and, at necropsy, there were obvious white patches on the lungs, which were histologically confirmed to be granulomas (of moderate–severe grade). Although the ageing study of Ncf2<sup>mla</sup> mice was compromised by the majority of them having to be humanely killed at a young age because of scratching, the few Ncf2<sup>mla</sup> mice that were not killed at an early age did live past the average age at which the Cyba<sup>mla</sup> mice had to be killed because of dyspnoea. It is interesting to note that we did not observe the presence of granulomas in the lungs of the bone marrow chimaeras, suggesting that this influx of macrophages resulting in granuloma formation is mediated by a non-haematopoietic component, possibly endothelial cells; Cyba is expressed by endothelial cells, and ROS can participate in vascular function [21].

Thus, in summary, we show that deficiency for any of the five subunits of the NOX2 complex results in decreased pulmonary metastatic colonisation. Focusing on Cyba-deficient and Ncf2-deficient mice revealed that the metastatic colonisation phenotype is mediated by the immune system, and, in support of this, the lungs of these mice showed elevated levels of activated effector T cells and NK cells. The lungs of these mice also showed granulomas even though they were housed in SPF conditions and in Cyba-deficient mice these granulomas led to decreased survival. Thus, the role of NOX2 is complex, and NOX2 deficiency affects multiple aspects of the pulmonary microenvironment that can have both favourable and unfavourable outcomes, which could help to explain the different lung manifestations seen in CGD.

Acknowledgements

This work was supported by grants from Cancer Research UK (C20510/A13031 to DJA), the Wellcome Trust (WT098051, to DJA) and ERC Combat Cancer (319661 to DJA). We thank Phillip Hawkins (Babraham Institute, UK) for kindly sharing the p40 knockout mouse line, Mahrokh Nohadani for histological processing of the samples and immunohistochemistry, David Thomas (University of Cambridge, UK) for advice and critical review of the manuscript, and members of the Research Support Facility at the Wellcome Sanger Institute for looking after the mice.

Author contributions statement

LvdW and AOS conceived the experiments, performed the experiments and wrote the manuscript. A Sw carried out experimental work. SC provided the experimental cohorts of Cybb mice and performed the intravenous injections of the bone marrow chimaeras. A Sc and GS provided the experimental cohorts of Ncf1 mice. MJA carried out the histopathological analysis and provided experimental advice. DJA provided experimental advice and supplied the Cyba and Ncf2 mouse lines. All authors helped to revise the manuscript.
