Sex differences in risk factor management of coronary heart disease across three regions

Min Zhao,1 Ilonca Vaartjes,2,3 Ian Graham,4 Diederick Grobbee,1,3 Wilko Spiering,5 Kerstin Klipstein-Grobusch,1,6 Mark Woodward,7,8 Sanne AE Peters7

ABSTRACT

Objective To investigate whether there are sex differences in risk factor management of patients with established coronary heart disease (CHD), and to assess demographic variations of any potential sex differences.

Methods Patients with CHD were recruited from Europe, Asia, and the Middle East between 2012-2013. Adherence to guideline-recommended treatment and lifestyle targets was assessed and summarised as a Cardiovascular Health Index Score (CHIS). Age-adjusted regression models were used to estimate odds ratios for women versus men in risk factor management.

Results 10 112 patients (29% women) were included. Compared with men, women were less likely to achieve targets for total cholesterol (OR 0.50, 95% CI 0.43 to 0.59), low-density lipoprotein cholesterol (OR 0.57, 95% CI 0.51 to 0.64), and glucose (OR 0.78, 95% CI 0.70 to 0.87), or to be physically active (OR 0.74, 95% CI 0.68 to 0.81) or non-obese (OR 0.82, 95% CI 0.74 to 0.90). In contrast, women had better control of blood pressure (OR 1.31, 95% CI 1.20 to 1.44) and were more likely to be a non-smoker (OR 1.93, 95% CI 1.67 to 2.22) than men. Overall, women were less likely than men to achieve all treatment targets (OR 0.75, 95% CI 0.60 to 0.93) or obtain an adequate CHIS (OR 0.81, 95% CI 0.73 to 0.91), but no significant differences were found for all lifestyle targets (OR 0.93, 95% CI 0.84 to 1.02). Sex disparities in reaching treatment targets were smaller in Europe than in Asia and the Middle East. Women in Asia were more likely than men to reach lifestyle targets, with opposing results in Europe and the Middle East.

Conclusions Risk factor management for the secondary prevention of CHD was generally worse in women than in men. The magnitude and direction of the sex differences varied by region.

INTRODUCTION

Coronary heart disease (CHD) remains one of the leading causes of death and disability worldwide. In 2015, 16% of all deaths in both men and women were caused by CHD.1 Individuals with established CHD are at high risk of further events and require intensive risk factor management.2 Despite convincing evidence on the major benefits of the management of modifiable risk factors in subjects with established CHD, an unacceptably large proportion of affected individuals do not reach guideline recommended risk factor targets.3-5

Previous studies in Western populations have suggested that the control of cardiovascular risk factors among patients with established CHD is generally even lower in women than in men.6-8 For example, results from EUROASPIRE III indicated that, despite similar treatment rates, women were less likely than men to achieve medical target levels. EUROASPIRE IV largely confirmed these findings and also reported that sex differences were primarily seen among individuals with a lower education level or at older age, suggesting a double burden among women in these populations. Despite the growing burden of CHD in non-Western countries, such as those in Asia and the Middle East, it remains unknown whether sex differences in risk factor control for the secondary prevention of CHD also exist across geographically diverse regions.

We therefore used data from the SURVEY of Risk Factors (SURF) Phase I audit to investigate whether there are sex differences in the management of CHD risk factors among patients with established CHD from three diverse regions.

METHODS

Study population

Details of the study protocol and methodology of SURF have been previously reported.4 Between 2012 and 2013, consecutive patients aged ≥18 years with established CHD (defined as a history of coronary artery bypass graft surgery (CABG), percutaneous coronary intervention (PCI), acute coronary syndromes (ACS), or stable angina) were recruited from routine outpatient cardiology clinics in 11 countries across three regions: Europe (Belgium, Croatia, Denmark, Ireland, Italy, Northern Ireland, Romania, and Russia); Asia (Taiwan and China); and the Middle East (Saudi Arabia). Data on demographics, self-reported smoking status, physical activity, attendance of cardiac rehabilitation, physical and laboratory measurements (ie, body anthropology, blood pressure (BP), cholesterol, blood glucose, and glycated haemoglobin (HbA1c)), and prescription of medications were obtained by trained research staff using standardised procedures.

Risk factor targets

The Joint European Societies guidelines were used to assess whether recommended targets for risk factor management were met.4-9 The BP target was <140/90 mmHg for patients without diabetes and <140/80 mmHg for patients with diabetes. The targets for total cholesterol (TC), low-density lipoprotein (LDL) cholesterol, and blood glucose were <3 mmol/L, <1.8 mmol/L, and <7 mmol/L, respectively. HbA1c was only collected for patients
Cardiac risk factors and prevention

with diabetes and its target was <7%. While the guideline does not define targets for high-density lipoprotein (HDL) cholesterol, values >1.0 mmol/L for men and >1.2 mmol/L for women were regarded as desirable. Obesity was defined as a body mass index (BMI) ≥30 kg/m² and central obesity was defined as waist circumference ≥88 cm for women and ≥102 cm for men. Adequate physical activity was defined as moderate or vigorous physical activity for at least 30 min three or more times a week.

A Cardiovascular Health Index Score (CHIS), adapted from the ideal Cardiovascular Health Score, was summarised to assess overall risk factor management. Since dietary information was not available, the CHIS included six risk factors: smoking status (current smoker vs non-smoker (never/ex-smoker)), BMI (obese vs not), physical activity (adequate vs not), BP (on target vs not), LDL cholesterol (on target vs not), and HbA1c/glucose (on target vs not). The number of risk factors on target could range from 0 to 6 and the risk factor profile was considered satisfactory if five or more risk factors were controlled. Additionally, risk factor control was assessed separately for therapeutic and lifestyle targets. 'All treatment targets' was defined as reaching targets for BP, LDL cholesterol, and HbA1c/glucose. 'All lifestyle targets' was defined as reaching targets for smoking status, BMI, and physical activity.

Statistical analyses

Patient characteristics were presented as means (SD) for continuous variables and as percentages for categorical variables, separately for men and women. Age-adjusted logistic regression analyses were used to obtain odds ratios (OR, 95% CI) of women versus men for sex associated with individual and combined risk factor targets. Men thus served as the reference group. Complete case analyses were conducted. Stratified analyses were performed by region (Europe, Asia, and the Middle East) and age group (≤65 years and >65 years). Effect modification was assessed by adding an interaction term to the model. In secondary analyses, we additionally adjusted for BP, smoking status, TC, HDL cholesterol, and glucose.

To assess the impact of medication use on therapeutic target achievements, the analyses on the target achievements of BP, TC and LDL cholesterol, glucose and HbA1c were stratified by the use of antihypertensive, lipid-lowering, and anti-diabetic medications, respectively. We also assessed whether the findings differed between defined CHD category (CABG, PCI, ACS, or stable angina). All analyses were performed with R version 3.2.2 and all tests were two tailed with statistical significance set at the 5% level.

RESULTS

A total of 10,112 patients, of whom 2,958 (29%) were women, were included. On average, women were 4 years older than men; more women than men had stable angina but fewer had CABG. Women more frequently had a history of hypertension and diabetes (table 1). Prescriptions of antplatelet and lipid lowering therapy were less frequent in women than men. The percentage of data not recorded was broadly similar between the sexes (supplementary eTable 1).

Achievement of risk factor targets

Control of cardiovascular risk factors was suboptimal in both men and women for all risk factors examined (figure 1). BP levels were on target in 45% of women and 38% of men. The corresponding age-adjusted OR was 1.31 (95% CI 1.20 to 1.44), indicating that women had a 31% higher odds of meeting the BP target than men. Women were also more likely than men to be non-smokers; the OR for being a non-smoker was 1.93 (95% CI 1.67 to 2.22). Among those with diabetes, there was no significant difference between the sexes in achieving the HbA1c targets (41% of women vs 43% of men). In contrast, a smaller percentage of women than men reached the treatment targets for TC (8% vs 14%), LDL cholesterol (22% vs 33%), and glucose (71% vs 76%), respectively. After adjustment for age, women had 50%, 43%, 22% lower odds than men of achieving TC, LDL cholesterol, and glucose targets (figure 1). Similarly, women had an 18% higher odds of being obese, a 26% lower odds of being physically active, and a 40% lower odds of attending cardiac rehabilitation than men. Overall, 6% of women and 8% of men reached all treatment targets and about one-third of men and women met all lifestyle targets; the ORs were 0.75 (95% CI 0.60 to 0.93) for all treatment targets and 0.93 (95% CI 0.84 to 1.02) for all lifestyle targets. Combined, 16% of women and 21% of men had an adequate CHIS, which corresponded to a 19% lower odds in women than in men (OR 0.81, 95% CI 0.73 to 0.91) (figure 2).

Findings were similar in the analyses adjusted for major risk factors (supplementary eFigure 1). Stratification of our analyses by medication use or CHD disease category did not materially change the results (supplementary eTable 2).

Sex differences by region

There was some indication that sex differences in the target achievements differed between regions (table 1 and figure 3). In Europe, the odds of achieving treatment targets for TC, LDL cholesterol, and glucose, respectively, were 34%, 31%, and 14% lower in women than men, compared with a 70%, 47%, and 30% lower odds for women in Asia, and a 76%, 53%, and 47% lower odds for achieving these targets for women in the Middle East. Sex differences in achieving all treatment targets were smallest in Europe and largest in the Middle East. Women in Asia and the Middle East were considerably more likely than men to be non-smokers, whereas no significant differences in smoking rates were observed between sexes in Europe (Asia: OR 11.5, 95% CI 7.4 to 19.0; Middle East: OR 16.2, 95% CI 6.7 to 53.4; Europe: OR 1.1, 95% CI 0.9 to 1.3). In Asia, women were more likely to be physically active than men. In contrast, women in Europe and the Middle East were less physically active than their male counterparts (figure 3). In Asia, women were more likely than men to meet all lifestyle targets, but the reverse was seen in Europe and the Middle East.

In Asia, the odds of having an adequate CHIS was 33% higher in women than men, compared with a 29% and 49% lower odds in women than men in Europe and the Middle East, respectively.

Sex differences by age

The sex differences in achieving treatment targets differed between those aged ≤65 years and those >65 years for TC, LDL cholesterol, and glucose, but not for other risk factors (figure 4). Compared with younger men, younger women were 59% less likely to meet the TC target, 53% less likely to meet the LDL cholesterol target, and 28% less likely to meet the glucose target. Corresponding results in those aged >65 years were 42%, 34%, and 18%, respectively. There was no evidence that women’s lower odds of meeting all treatment targets, all lifestyle targets, or having an adequate CHIS, compared with men, differed between those aged ≤65 versus >65 years.

Sex differences by age and region

Regional differences in achieving treatment and lifestyle targets varied between younger and older individuals.
Table 1  Patient characteristics and cardiovascular risk factors, stratified by sex and region

| Total No. | Overall | Europe | Asia | Middle East |
|-----------|---------|--------|------|-------------|
|           | Men     | Women  | Men  | Women       | Men | Women |
| Age (years) | 64.2 (11.2) | 67.5 (10.9) | 64.4 (10.8) | 68.3 (10.8) | 66.3 (11.7) | 67.7 (10.1) | 61.6 (11.9) | 63.5 (12.2) |
| Disease category |
| CABG | 22.3 | 12.8 | 24.0 | 14.8 | 7.7 | 3.8 | 28.2 | 20.3 |

Continued
Cardiac risk factors and prevention

Due to higher smoking prevalence in younger men, in Asia and the Middle East, sex differences in smoking rates tended to be larger in those aged ≤65 years than in those aged >65 years in these regions. In Europe and the Middle East, sex differences in overall risk factor management, to women’s disadvantage, were larger among younger than among older individuals. In Asia, the odds of adequate overall risk factor management (i.e., a good CHIS) was higher among younger women than younger men, which was largely driven by better control of lifestyle factors in women. In older women in Asia, the odds of adequate risk factor management was lower than in their male counterparts.

**DISCUSSION**

The present study among over 10,000 individuals with CHD indicated that, overall, risk factor management for the secondary prevention of CHD is worse among women than men. However, the magnitude and direction of the sex differences in the likelihood of meeting guideline-recommended targets varied across component treatment and lifestyle targets. BP control was better in women than in men whereas women were less likely to reach target lipid and glucose levels. Sex differences in risk factor management also varied across regions, with contrasting patterns for treatment and lifestyle targets.

Previous studies on sex differences in risk factor management for the secondary prevention of CHD have also shown that women, in general, have a worse risk factor profile and are less likely to meet therapeutic targets than men. The EUROASPIRE III and IV, two large surveys on the control of cardiovascular risk factors among coronary patients across Europe, reported that women were less likely than men to achieve target lipid and HbA1c levels. Additionally, EUROASPIRE IV demonstrated that the largest sex differences were seen among elderly patients and among those with lower levels of education. EUROASPIRE III reported that BP control was also worse among women than men, whereas EUROASPIRE IV found similar rates between sexes. In the present study, we found that, although BP levels were higher among women than men, BP control was considerably better in women than in men. Lipid and glucose targets, however, were less likely to be achieved by women than men.

Sex differences in the availability of evidence-based medications may be responsible for women’s lower likelihood of achieving treatment targets. While the EUROASPIRE surveys reported broadly similar treatment rates between sexes, our results are consistent with several other studies indicating lower rates of medication use in women than men. For instance, the CRUSADE study, a large national study involving 36,000 coronary patients in the USA, demonstrated that women were less likely than men to receive aspirin, ACE inhibitors, or statins at hospital discharge after a cardiac event, even after adjustment for women’s worse cardiovascular risk profile at admission. Moreover, a study among 15,000 coronary patients in the Netherlands found persistent sex differences in the use of lipid-lowering and antiplatelet medications, particularly in younger patients. Others also reported that women were less likely than men to receive intensive lipid-lowering therapy in order to achieve their optimal lipid goals. However, our analyses stratified by medication use did not alter our main findings on sex differences in risk factor management; nevertheless, the prevalence of medication use differs between sexes.

Despite this, as shown in our findings that women with CHD tended to be older, women’s older age at the diagnosis of CHD with more comorbidities might also explain their lower
Cardiac risk factors and prevention

| Risk factors                  | Women(%) | Men(%) | Odds ratio[95% CI] |
|------------------------------|----------|--------|-------------------|
| Treatment target             |          |        |                   |
| BP on target                 | 45       | 38     | 1.31 [1.20, 1.44] |
| TC on target                 | 8        | 14     | 0.50 [0.43, 0.59] |
| LDL on target                | 22       | 33     | 0.57 [0.51, 0.64] |
| HDL on target                | 51       | 54     | 0.83 [0.75, 0.92] |
| Glucose on target            | 71       | 76     | 0.78 [0.70, 0.87] |
| HbA1c on target              | 41       | 43     | 0.92 [0.75, 1.14] |
| All treatment targets        | 6        | 8      | 0.75 [0.60, 0.93] |
| Lifestyle                    |          |        |                   |
| Non-smoker                   | 90       | 81     | 1.93 [1.67, 2.22] |
| Adequate physical activities | 48       | 56     | 0.74 [0.68, 0.81] |
| Non-obese                    | 69       | 71     | 0.82 [0.74, 0.90] |
| Non-central obese            | 32       | 47     | 0.54 [0.49, 0.59] |
| Cardiac rehabilitation       | 23       | 33     | 0.60 [0.54, 0.66] |
| All lifestyle targets        | 32       | 34     | 0.93 [0.84, 1.02] |

Figure 1  Age-adjusted sex differences in risk factor management. Target blood pressure (BP) was defined as BP <140/90 mmHg in those without diabetes or <140/80 mmHg in those with diabetes. The target for total cholesterol (TC), low-density lipoprotein (LDL) cholesterol and high-density lipoprotein (HDL) cholesterol levels were defined as <3 mmol/L, <1.8 mmol/L, and >1.0 mmol/L for men and >1.2 mmol/L for women, respectively. Target glucose was defined as <7 mmol/L. Information on glycated haemoglobin (HbA1c) was only collected from patients with diabetes and its target was defined as <7%. Achieving all three medical targets (BP on target, LDL on target, and glucose/HbA1c on target) was defined as ‘All treatment targets’. Obesity was defined as a body mass index (BMI) ≥30 kg/m² and central obesity was defined as waist circumference ≥88 cm for women and ≥102 cm for men. Smoking status was current smoker and non-smoker. Adequate physical activity level was defined as moderate or vigorous physical activity for at least 30 min three or more times a week. Reaching all three lifestyle targets (non-smoker, adequate physical activities, and non-obesity) was defined as ‘All lifestyle targets’. Odds ratios (95% CI) presented as women versus men.

Figure 2  Age-adjusted sex differences in Cardiovascular Health Index Score (CHIS). The CHIS included six risk factors: smoking status (current smoker or non-smoker), body mass index (obese or not), physical activity (adequate or not), blood pressure (on target or not), low-density lipoprotein (LDL) cholesterol (on target or not), and HbA1c/glucose (on target or not). The number of controlled risk factors was summed, ranging from 0 to 6. A good CHIS was defined as five or more risk factors controlled (CHIS=5 or 6). Odds ratios (95% CI) presented as women versus men; p values are for interaction between subgroups.

Figure 3  Age-adjusted sex differences on treatment targets and lifestyle factor management, stratified by region. Conventions as in figure 1. Odds ratios (95% CI) presented as women versus men; p values are for interaction between subgroups.

men and fewer female CABG patients were recruited. As such, women may pay less attention to their CHD risk factor management, resulting in less cardiovascular medication being used and fewer targets being achieved by women. This is unfortunate as clinical guidelines recommend, based on evidence from large randomised controlled trials, the use of preventative medications and a strategy of CHD prevention for all CHD patients, irrespective of age, sex, or severity of disease.2 20

Most previous studies on sex differences in cardiovascular risk management have been conducted in Western populations. Our study not only showed that substantial sex differences in cardiovascular risk management exist in Europe, Asia and the Middle East, but also indicated that regional variations in the size and direction of these sex disparities are present. Sex differences in smoking habits varied most notably across regions; while the prevalence of smoking was similar between the sexes in Europe, women in Asia and the Middle East were considerably less likely to smoke than their male counterparts. In contrast, sex disparities in the achievement of treatment targets were smaller in Europe than in Asia and the Middle East, especially for lipid and glucose levels. Lack of knowledge among female patients about their disease or the necessity of adequate guideline-recommended treatment could contribute to these sex differences in risk factor management.19 21–24 A survey in the USA found that only 53% of women were aware that CHD is the leading cause of death in women and less than half of the women were...
familiar with optimal levels of CHD risk factors. Additionally, a 12-year follow-up survey in the USA showed that the majority of women did not adhere to appropriate secondary prevention and often used non-evidence-based therapies to prevent CHD. Comparative studies among men have not been conducted, and neither are there robust data on the awareness of CHD risk among women, and men, from non-Western populations. However, it is conceivable that women’s awareness of CHD risk and the benefits of the management of major risk factors is particularly low in non-Western populations, where CHD rates are increasingly rising, risk factor profiles are different, and the uptake of preventive strategies remains lower than in the West. Greater knowledge and awareness of CHD in women, better understanding of regional differences, as well as more widespread use of women-specific clinical guidelines appropriate to local settings, could help to decrease the sex disparities in CHD risk factor management and could improve CHD outcomes in both men and women.

SURF, a pragmatic clinical audit, is undertaken as part of routine clinics at low cost and minimal increase in workload, aiming to document and investigate CHD risk factor management for secondary prevention. It is particularly suitable as an audit instrument for use in low-resource settings and facilitates multiple comparisons of risk factor management across different regions and, in future iterations, over time. Some limitations of SURF deserve to be mentioned. Unlike EUROASPIRE, SURF data are collected during outpatient visits and laboratory measurements are not performed with a standardised scientific methodology. Although the high frequency of missing data might reduce the reliability of prevalence estimates, the percentage of missing data within each region was broadly similar between sexes, and hence it is unlikely to alter our conclusions. Moreover, participating centres were identified through personal contact and may not be representative of healthcare facilities treating CHD patients in participating countries. Finally, more than 60% of patients were recruited from European centres. While these limitations may have affected the descriptive characteristics, the comparisons of sex differences in cardiovascular risk factor management are less likely to be affected. A new phase of SURF, SURF II, will increase representativeness both in terms of patient participation and by allowing the participation of a wide variety of centres, irrespective of size and resources.

CONCLUSION
We observed substantial differences between men and women in cardiovascular risk factor management for the secondary prevention of CHD, most often to the detriment of women. Sex disparities in risk factor management differed across regions, suggesting the need for tailored strategies to reduce these inequalities and to improve the uptake of guideline-recommended care for the secondary prevention of CHD in both men and women.
