INTRODUCTION: Skull defects most commonly result from trauma. Contaminated compound depressed skull fractures among civilians and penetrating head injuries among military personnel are the most frequent types. Among the possible indications for cranioplasty, the two commonly accepted ones, address issues of cerebral protection and appearance. The "Syndrome of the trephined," consisting of headaches, dizziness, intolerance, vibration and noise, irritability, fatiguability, loss of motivation and concentration, depression, and anxiety, universally accepted as an indication to reconstruct the skull.\textsuperscript{1,2}

Four persuasive indications for cranioplasty, are restoration of cerebral protection, physical appearance, intracranial pressure relationships and the provision of an intact vault for the normal growth and development of cephalic structures in the young. Evidence supporting the organic basis of the syndrome of the trephined is the improvement in symptoms following cranioplasty with the reversion of intracranial pressure relationships to normal. Improvement in, electroencephalographic abnormalities, seizures, and neurological dysfunction (motor, speech) has been reported.\textsuperscript{1,3,4}

Contraindications to cranioplasty include the presence of hydrocephalus, cerebral swelling, infection, a compound wound, contiguous functional paranasal sinuses (as indicated by air in a sinus on x-ray), and thin, scarred, or devitalized scalp. The timing of cranioplasty is critical for avoiding the development of infection in devitalized autografts or around alloplastic materials. It is generally accepted that cranioplastys should be delayed 3 to 6 months after compound wounds and at least 1 year after a wound infection.

MATERIAL AND METHODS: The variables recorded were: age, sex, site, original diagnosis, site of defect, interval between craniectomy and cranioplasty, pre-operative symptoms, intra operative,
post-operative complications and cosmetic grading. All the skull defects were hemicranial (Involving more than two regions on one side).

**Inclusion Criteria:** All traumatic intracerebral haemorrhages, hypertensive intracerebral haemorrhages.

**Exclusion Criteria:** Cases with cardiovascular disorder, depressed skull fractures, age less than 16 years.

**Cranioplasty Procedure:** The patient’s head is fully shaved and prophylactic intravenous antibiotic is given prior to surgery. Old craniectomy scar is used as incision site. A scalp flap is carefully separated from the dura using sharp dissection, avoiding injury to the dura and the cranial defect is entirely exposed. Dural defects are repaired with watertight sutures or with pericranial fascia. A periosteal incision is made near the defects margin and reflected about 1-2cm away. In order to obtain good approximation of the cranioplastic plate, 3 to 5mm of outer table of defect edge is often trimmed. The cranial defect is measured intraoperatively.

Methyl methacrylate is prepared by mixing the liquid monomer (Catalyst) with the powder polymer. This mixture is constantly stirred until its consistency is doughy (Within 15 minutes). It is then place in between plastic layers and moulded according to the cranial defect with minimum 3 to 5mm thickness. The cranioplastic plate edge is trimmed with a Mayo scissors before it solidifies. Multiple angled holes are made through the outer cortical bone and acrylic plate. A nonabsorbable polyester suture material such as ETHIBOND™ 3/0 and titanium wires are inserted through the drill holes and used to hold the cranioplasty plate in position. A subgaleal suction drain is placed and the flap closed in two layers. The subgaleal drain will be removed after 48 hours.

**Cosmetic Grading:** Grading system for cosmetic outcomes.\(^5\)

| Grade | Components                                                      |
|-------|-----------------------------------------------------------------|
| A     | No evidence of surgery with mild prominence of temporalis       |
| B     | Slight depression of temporalis fossa                           |
| C     | Marked depression of temporalis fossa with suggestion of zygomatic process |
| D     | Atrophy of temporalis muscle                                    |
| E     | Atrophy with sliding/rooting of temporalis.                     |

**RESULTS AND ANALYSIS:** This study includes total no of 43 patients, out of which 40 were male and 3 were female patients. 11 patients had pre-operative symptoms, out of which 3 patients had only headache and 8 patients had “syndrome of trephined”. This is shown in table 1.

| PREOPERATIVE SYMPTOMS    | No. of Patients | Percentage |
|--------------------------|-----------------|------------|
| HEAD ACHE                | 3               | 6.97       |
| SYNDROME OF TREPINE      | 8               | 18.60      |

Table 1: Pre-operative Symptoms
Out of 43 patients 38 patients comes under grade A, i.e. No evidence of surgery with mild prominence of temporalsis and remaining 5 patients comes under grade B, that is Slight depression of temporalsis fossa. This is shown in table no 2.

| Cosmetic Grading | No. of patients | Percentage |
|------------------|-----------------|------------|
| Grade A          | 38              | 88.37      |
| Grade B          | 5               | 11.63      |

Table 2: Post-Operative Cosmetic Results

The median time interval between cranioplasty and initial surgery is 9 months. Intraoperative dural tear occurred in two patients. Post-operative loosening of the graft seen in 4 patients and post-operative subgaleal collection is seen in 4 patients. Post-operative seizures were seen in 2 patients.

| Post-operative complications          | No. of Patients | Percentage |
|---------------------------------------|-----------------|------------|
| Headache                              | 0               | 0          |
| Post-operative Wound Healing Problems | 0               | 0          |
| Post-operative CSF leak               | 0               | 0          |
| Post-operative infection like meningitis | 0           | 0          |
| Post-operative loosening of graft     | 4               | 9.3        |
| Post-operative subgaleal collection   | 4               | 9.3        |
| Post-operative seizures               | 2               | 11.63      |

Table 3: Post-Operative Complications

DISCUSSION: Common indication for decompressive craniectomies include traumatic brain injuries following road traffic accidents. In our study 39 patients underwent decompressive craniectomy following traumatic brain injury for road traffic accidents, 4 patients underwent decompressive craniectomy following hypertensive gangliocapsular bleed. Meticulous cranioplasty is important for good cosmetic results, as well as long-term protection of brain from external environment.

Cerebral blood flow, brain metabolism, as well as neurological status are affected by the outside pressure in patients with skull defects. In our study 8 patients with “Syndrome of trephined” reported that they had improved after cranioplasty. Their main complaints of headache, insomnia, mental depression and local discomfort on movement had diminished. Hemiparesis improved in 3 patients. Others remained unchanged after cranioplasty.

Methyl methacrylate was first used as a cranioplastic material by Zander in 1940. The major advantage of methyl methacrylate is, it is completely malleable in the initial stages of hardening, and thus can be moulded easily during surgery to fit the contour defects. It is relatively cheaper, biologically inert and does not interfere with computed tomography or magnetic resonance imaging studies.

The autopolymerization of methyl methacrylate during its preparation can cause thermal damage to the underlying brain due to its exothermic reaction. However, the acrylic can be irrigated with saline until it solidifies and can be safely put on the dura. In our study there was 4 loosening of grafts. The use of struts with titanium mesh, stainless steel mesh or miniplates have been advocated,
as a scaffold to improve the mechanical strength and cosmetic results, but this technique is more costly.

In our study 4 patients had loosening of the graft initially, when we used non absorbable suture material to hold the acrylic plate to the cortical bone. Later we used titanium wires to fix the acrylic plate to the cortical bone for preventing the loosening of the graft. After using Titanium wires to fix the acrylic plate to the cortical bone, there was no loosening of the grafts.

Complications from cranioplasty may be divided between those characteristic of the operative procedure in general and those related more to the type of implant used. Intra operative dural tear is seen in 2 patients. We closed with muscle graft before implantion of acrylic plate. The reported infection rate for methyl methacrylate is 3.8 to 12%. In our study there are no cases of post operative wound healing problems, post operative CSF leak, post operative infection. The reported post-operative subgaleal collection after removal of drain is 12%. In our study post-operative subgaleal collection is seen in 4 patients (9.3%) and post operative seizures seen in 2 patients. The subgaleal collection resolved itself by applying compression dressing and post operative seizures were controlled by adequate dosage of antiepileptics.

We have adapted Raza et al grading system for cosmetic outcome. 4 patients had grade B where we used non absorbable suture material to hold the acrylic plate to the cortical bone, and remaining 39 patients had grade A where we used titanium wires to fix the acrylic plate to the cortical bone.

CONCLUSION: Methylmethacrylate cranioplasty is relatively safe, inexpensive, biologically inert and provides an excellent aesthetic reconstructive option.
