Abstract. The detection of a nuclear spin in an individual molecule represents a key challenge in physics and biology whose solution has been pursued for many years. The small magnetic moment of a single nucleus and the unavoidable environmental noise present the key obstacles for its realization. In this paper, we demonstrate theoretically that a single nitrogen-vacancy center in diamond can be used to construct a nano-scale single-molecule spectrometer that is capable of detecting the position and spin state of a single nucleus and can determine the distance and alignment of a nuclear or electron spin pair. The proposed device would find applications in single-molecule spectroscopy in chemistry and biology, for example in determining the protein structure or in monitoring macromolecular motions, and can thus provide a tool to help unravel the microscopic mechanisms underlying bio-molecular function.
1. Introduction

As single nuclei have exceedingly small magnetic moments, a large ensemble (typically $10^{18}$ nuclear spins) is necessary to obtain an observable signal employing methods such as magnetic resonance spectroscopy (NMR). As a consequence, chemical and biological processes have usually been tracked with ensemble measurements, which only provide ensemble averages and distribution information. Single-molecule studies can instead allow one to learn structural information and time trajectories of individual molecules free of natural disorder [1–4]. The detection of a single nucleus in a single molecule can thus provide various new possibilities for single-molecule spectroscopy. Furthermore, single nuclear spins have long coherence time due to their weak coupling with the environment, which makes them promising candidates for a qubit or a quantum register. For example, it has been proposed to engineer nitrogen nuclear spin in the molecule of $^{14}$N@C$_{60}$ [5, 6] or phosphorus donor [7] as a qubit candidate. For these purposes, efficient readout of the nitrogen nuclear spin state of a single molecule is crucial.

Nitrogen-vacancy (NV) centers in diamond have been used to construct ultrasensitive nanoscale magnetometers [8–13], and have led to interesting applications in nano imaging [14, 15] and biology as well [16–18]. NV centers in diamond benefit from long coherence times at room temperature and highly developed techniques for coherent control, noise decoupling schemes and optical readout of their electron spins. A single NV center can be used to detect a single external electron spin [19] and a proximal nuclear spin (within a few atom shells) [20–22]. It has also been shown that it is possible to detect a strongly coupled nuclear spin pair [23] and measure noise spectra [24–28] by applying dynamical decoupling pulses. The schemes based on decoupling pulses may nevertheless suffer various constraints such as the limited achievable repetition rate of pulses and the power requirement. As a consequence, the detection of individual nuclear spins in the presence of realistic environments remains a challenging task. The key obstacles originate firstly from the requirement that coherence times are sufficiently long in order to observe the effect of single nuclei on the NV spin. The second key obstacle lies...
in the difficulty of distinguishing a distant nuclear spin from other environmental nuclei that couple to the NV spin.

In this work, we address both challenges by continuously driving a single NV electron spin and use it as a probe to measure a specific transition frequency of the target system. The role of continuous driving is twofold: firstly, it decouples the NV spin from the unwanted influence of a spin bath (which is particularly strong for NV centers located close to the surface [19]) to achieve sufficiently long coherence times [29–35]; secondly, by changing the Rabi frequency of the external driving field we can tune the NV spin to match the target frequency and thus selectively enhance the sensitivity for this specific frequency which allows us to single out the target nucleus. With this scheme, we are able to determine the position of a single nucleus in the presence of a realistic environment. We demonstrate how to use this mechanism to implement quantum non-demolition measurement of a single nitrogen nuclear spin state in a cage molecule of fullerene (14N@C60). This is achieved by exploiting the fact that the flip-flop process between the NV spin and the target system will either be allowed or prohibited dependent on the nuclear spin state for a specific NV spin initial state. Our proposed detector can be applied straightforwardly to the determination of the distance and alignment of a spin pair. We show that the present model can find applications in single-molecule spectroscopy with organic spin labels. It can also be used to witness the creation and recombination of charge separate state in radical pair reactions [36]. We expect that the present diamond-based single-molecule probe will find more potential applications in determining the protein structure and monitoring chemical (biological) processes; see examples of molecular motors, ATPase and RNA folding in [37–39].

2. Basic model of the nitrogen-vacancy center spectrometer

The probe in our model is an NV center spin in diamond, whose ground state is a spin-1 with a zero-field splitting of 2.87 GHz. By applying an additional magnetic field, one can lift the degeneracy of \( |m_s = -1 \rangle \) and \( |m_s = +1 \rangle \) and thus allow selective driving with a continuous microwave field of one specific electronic transition, e.g. \( |m_s = 0 \rangle \leftrightarrow |m_s = +1 \rangle \) (henceforth denoted by \( |\downarrow\rangle \) and \( |\uparrow\rangle \), respectively). Within the \( |\downarrow\rangle \), \( |\uparrow\rangle \) subspace the Hamiltonian of the driving field can be written as \( H_{\text{NV}} = \Delta_\sigma \sigma \), where \( \sigma = \begin{pmatrix} 1 & 1 \end{pmatrix} \begin{pmatrix} \downarrow \downarrow \uparrow \end{pmatrix} \begin{pmatrix} \uparrow \downarrow \downarrow \end{pmatrix} \) is the spin-1/2 operator and the eigenstates (\( |\uparrow\rangle \) and \( |\downarrow\rangle \)) represent the dressed states of the system. We remark that different driving schemes may be used depending on the properties of target systems as we will discuss later, see section 4. Our goal is to use such an NV dressed spin as a probe to detect a specific frequency in the target system. The magnetic dipole–dipole interaction between the NV spin and another spin is \( H_{\text{NV–S}} = \sum_N g_N [3(\mathbf{S} \cdot \hat{r}_N)(\mathbf{I}_N \cdot \hat{r}_N) - \mathbf{S} \cdot \mathbf{I}_N] \), where \( \mathbf{S}, \mathbf{I}_N \) are the NV spin and target spin operators, and the interaction strength is \( g_N = -\hbar \mu_0 \gamma_N \gamma_R / (4 \pi r_N^3) \), wth \( \gamma_N \) and \( \gamma_R \) the gyromagnetic ratio of the electron spin and target spin, respectively. The vector \( \hat{r}_N = r_N \hat{r}_N \), with the unit vector \( \hat{r}_N = (r_N^x, r_N^y, r_N^z) \), connects the NV center and the target spin. The large zero-field splitting leads to an energy mismatch which prohibits direct NV spin flip-flop dynamics and allows for the secular approximation to simplify the NV–target spin interaction as follows:

\[
H_{\text{NV–S}} = \mathbf{S} \cdot \sum_N g_N \left[ 3r_z (r_N^x \mathbf{I}_N^x + r_N^y \mathbf{I}_N^y) + (3(r_N^z)^2 - 1) \mathbf{I}_N^z \right].
\]

The coupling operator \( \mathbf{S} \), leads to dephasing-type interaction in the original NV spin basis but induces flips of NV dressed spin (see figure 1). The flip-flop process will be most efficient when

---

Figure 1. Basic model of an NV center spectrometer. We apply a continuous field to drive the electronic transition $|m_s = 0⟩ \leftrightarrow |m_s = +1⟩$, which provides an effective dressed spin-$\frac{1}{2}$. When the Rabi frequency $\Omega$ is on resonance with one specific transition frequency of the target system, the flip-flop process will happen between the dressed NV spin and the target system, which leads to a change of the NV dressed state population that can be measured via spin-dependent fluorescence of the NV spin.

the Rabi frequency $\Omega$, i.e. the energy splitting of the dressed states $(|\uparrow⟩, |\downarrow⟩)$, matches the transition frequency of the system spin that we wish to probe [40]. Therefore, one can initialize the NV spin in one of the dressed states and tune the Rabi frequency to determine the transition frequency of the target system by measuring the probability that the NV spin remains in the initial state. The position of the target spin (i.e. the information on the vector $\vec{r}_N$) can be inferred from the flip-flop rate of the NV center if the magnetic moment is known. We remark that continuous driving, on the one hand, achieves the selective coupling between the NV center and the target nuclear spin and, on the other hand, decouples the NV center from the other species of spins due to the mismatch of the Hartmann–Hahn resonant condition. The residual effect of the environmental spins is suppressed to be of the order of $\sim \delta^2/(\Omega - \omega)$, where $\delta$ represents the magnetic noise from the environmental spin and $\omega$ denotes its Larmor frequency (see the appendix for a simple example that demonstrates the decoupling efficiency of continuous driving).
3. Measure the position of a single nucleus

3.1. Work principles

We first apply our idea to determine the position of a single nucleus via the flip-flop process between the NV dressed spin and the target spin. This is particularly interesting in biology, for example in determining where certain important nuclei (e.g. $^{14}$N, $^{31}$P) are located in the protein complex. We introduce the hyperfine vector $\hat{h}(\theta_0, \phi_0)$, which is determined by the unit vector $\hat{r}(r_x, r_y, r_z)$ that connects the NV center and the target spin as

$$\cos \theta_0 = \frac{3r_z^2 - 1}{\sqrt{3r_z^2 + 1}},$$

$$\sin \theta_0 \cos \phi_0 = \frac{3r_x r_z}{\sqrt{3r_z^2 + 1}},$$

$$\sin \theta_0 \sin \phi_0 = \frac{3r_y r_z}{\sqrt{3r_z^2 + 1}}.$$

The effective total Hamiltonian is thus rewritten as

$$H_E = \Omega S_z - (\gamma N B) I_N \cdot \hat{b}(\theta, \phi) + \left( g N \sqrt{3r_z^2 + 1} \right) S_z \left[ \hat{h}(\theta_0, \phi_0) \cdot I_N \right],$$

where $\hat{b}(\theta, \phi)$ denotes the direction of the magnetic field. Note that $S_z = |+1\rangle \langle +1| = \frac{1}{2} I + \sigma_z$ where $\sigma_z$ is the spin-$\frac{1}{2}$ operator; thus the above Hamiltonian is

$$H_E = \Omega S_z - \gamma_N B_e(\theta_e, \phi_e) \cdot I_N + \frac{1}{2} \left( g N \sqrt{3r_z^2 + 1} \right) \sigma_z \left[ \hat{h}(\theta_0, \phi_0) \cdot I_N \right],$$

where the effective nuclear spin Larmor frequency is given by $B_e = B(\theta, \phi) - \frac{1}{3} \left( g N \sqrt{3r_z^2 + 1} \right) \hat{h}(\theta_0, \phi_0)$. We choose the driving amplitude $\Omega_0$ on resonance with the Larmor frequency of the target nuclear spin to satisfy the Hartmann–Hahn matching condition $\Omega = \gamma N B_e$ [40]. To measure the position of the target spin, we first prepare the NV spin in the initial state $|\uparrow\rangle_x = \frac{1}{\sqrt{2}} (|0\rangle + |1\rangle)$ and assume that the nuclear spin is in the thermal state, which is well approximated by $\rho_N(0) = \frac{1}{2} I$ at room temperature. If the effective nuclear spin Larmor frequency is much larger than the NV–nuclear spin coupling (i.e. $\omega_N = \Omega \gg g_N$), the energy unconserved interactions between the NV spin and the nuclear spin are greatly suppressed, and the flip-flop process is dominant. After time $t$, we measure the probability that the NV spin remains in the state $|\uparrow\rangle_x$ which depends on the coupling strength $J$ as follows:

$$S(t) = \frac{1}{2} + \frac{1 + \cos (Jt)}{4}.$$

From the signal $S(t)$, one can infer the value of $J$ that depends on the distance and direction of the nuclear spin to NV center

$$J = \frac{1}{4} \left( g N \sqrt{3r_z^2 + 1} \right) \left[ 1 - \left| \hat{h}(\theta_0, \phi_0) \cdot \hat{b}(\theta_e, \phi_e) \right|^2 \right]^{1/2}.$$

The spin flip-flop rate $J$ as in equation (8) depends on the direction of the effective magnetic field $(\theta_e, \phi_e)$. In the case where the applied magnetic field is much larger than the nuclear field...
energy shift induced by NV spin, the direction \((\theta, \phi)\) can be approximated well by the applied magnetic field direction \(\hat{b}(\theta, \phi)\). It can be seen that if and only if the magnetic field direction \((\theta, \phi)\) is in parallel (or anti-parallel) with the hyperfine vector, namely \(\theta = \theta_0(\pi - \theta_0)\) and \(\phi = \phi_0(2\pi - \phi_0)\), the effective flip-flop rate vanishes \(J = 0\) even though the Hartmann–Hahn resonance condition is still satisfied. If the magnetic field is orthogonal to the hyperfine vector, the flip-flop rate is maximal as \(J_m = \frac{1}{4} \left(gN\sqrt{3r_e^2 + 1}\right)\). By choosing a set of magnetic field directions \(\hat{b}(\theta, \phi)\), one can obtain the projection of hyperfine interaction along different directions, from which one can derive the direction vector of the target spin \((r_x, r_y, r_z)\) with respect to the NV center. We remark that when the applied field is not along the NV axis, the eigenstates of NV are in general not the eigenstates of the spin operator \(S_\perp\). This may affect e.g. the efficiency of NV spin measurement and limit the highest magnetic field applied. One possible way of compensating is to apply additional pulses to map the eigenstates of NV to the one of the spin operator \(S_\perp\).

We remarked that the fluctuation in the driving field \((\Omega)\) will limit the measurement precision. One way of overcoming this problem is to use the high-order dressed spin from concatenated dynamical decoupling as proposed in [34] as a probe. For example, we can use a second-order sequential driving scheme with the first-order driving field \(H_{OL} = \Omega_1 \cos(\omega t) \sigma_z\) and a second-order driving field as \(H_{OL} = 2\Omega_2 \cos\left(\omega t + \frac{\pi}{2}\right) \cos(\Omega_1 t) \sigma_x\), which can suppress the effect of the first driving field fluctuation [34]. In the second-order interaction picture, we can tune the Rabi frequencies to satisfy the Hartmann–Hahn resonant condition as \(\Omega_1 + \Omega_2 = \omega_N\), and the coupling operator of the NV spin with the target spin becomes

\[
\sigma_z \rightarrow \frac{1}{2} \exp\left[i(\Omega_1 + \Omega_2)\right]|+\rangle \langle -| + \text{h.c.}
\]

The energy gap of the second-order dressed spin \(|+\rangle, |-\rangle\) is more robust against the driving field fluctuation [34], and thus enables our scheme to work with a higher accuracy. With higher order decoupling, it is even possible to achieve \(T_1\) limit coherence time. The required measurement time \(t\) is constrained by \(T_1\), which can well exceed a few ms for NV centers [41].

### 3.2. Measure a single \(^{31}\text{P}\) position in the molecule of \(^1\text{H}_3^{31}\text{PO}_4\)

We demonstrate our idea by showing how to use an NV spin to measure the position of \(^{31}\text{P}\) in a single molecule \(^1\text{H}_3^{31}\text{PO}_4\). Due to its half-integer nuclear spin and high abundance of \(^{31}\text{P}\), NMR spectroscopy based on phosphorus-31 has become a useful tool in studies of biological samples. Phosphorus is commonly found in organic compounds, coordination complexes and proteins, such as phosphatidyl choline which is the major component of lecithin. In \(^1\text{H}_3^{31}\text{PO}_4\), \(^{31}\text{P}\) interacts with a few adjacent hydrogen atoms, which captures generic features of the protein. Thus it can serve as a paradigmatic example for practical applications of our model. For \(^{31}\text{P}\) and \(^1\text{H}\), the coupling strength is \(g = 48.6(6.075)\) kHz for the distance \(R_m = 0.1(0.2)\) nm, which is relatively strong as compared to the coupling between the NV spin and the target \(^{31}\text{P}\) spin. The sole information about the position of \(^{31}\text{P}\) is blurred by such a strong interaction, see figure 2(a). We can apply a strong magnetic field such that \((\gamma_H - \gamma_{31}\text{P})B \gg g_m\), which suppresses the hopping interaction between the target nuclear spins and its neighboring hydrogen nuclei. The effective Hamiltonian of the target system thus becomes

\[
H_S = -\gamma_N \mathbf{B} \cdot \mathbf{I}_N - \gamma_m \mathbf{B} \cdot \sum_m \mathbf{I}_m + \sum_m g_m \left(1 - 3r_e^2\right) \mathbf{I}_m \mathbf{I}_N,
\]
Figure 2. Measure the position of a single nucleus $^{31}\text{P}$ in a $^{1}\text{H}_2^{31}\text{PO}_4$ molecule at a distance of $d = 5$ nm from the NV center. (a) The signal $S(t)$ measured at time $t = 3$ ms for different magnetic field directions as described by $(\theta, \phi)$ without radio frequency driving on resonance with the Larmor frequency of $^{1}\text{H}$. The driving amplitude on the NV spin is $\Omega = 500$ kHz. (b) The signal $S(t)$ measured at time $t = 3$ ms for different magnetic field directions $(\theta, \phi)$ with the application of radio frequency driving (20 kHz) on resonance with the Larmor frequency of $^{1}\text{H}$. The driving amplitude on NV spin is tuned to be on resonance with the Larmor frequency of $^{31}\text{P}$ at $\omega = \gamma_{31}\text{P}B = 500$ kHz with $B = 290$ G. The hyperfine vector is in the direction of $\theta_0 = 68.233^\circ$ and $\phi_0 = 93.841^\circ$. (b) The signal $S$ as a function of time $t$ with the magnetic field direction chosen to be orthogonal to the hyperfine vector. The estimated value of $J$ is 0.2041 kHz, which is in good agreement with the exact value 0.2065 kHz.

where $I_N$ and $I_m$ denote the spin operator of $^{31}\text{P}$ and $^{1}\text{H}$, respectively. To eliminate the line broadening (i.e. the last term of equation (10)), we propose to drive the hydrogen nuclei continuously. Since the Larmor frequencies can be made sufficiently different for $^{31}\text{P}$ and $^{1}\text{H}$, it is possible for us to selectively drive the hydrogen nuclear spins while not affecting the target $^{31}\text{P}$ nucleus due to a large detuning. This leads to the system Hamiltonian as follows:

$$H_S = -\gamma_N B \cdot I_N + \Omega_1 \cdot \sum_m \Gamma_m I_m + \sum_m g_m (1 - 3r_z^2) \Gamma_m I_N.$$

(11)

If the Rabi frequency $\Omega_1$ is large enough, the interaction term $\Gamma_m I_N$ can be effectively averaged out and eliminated. We remark that one can also drive the target $^{31}\text{P}$ nuclear spin which can also suppress the line broadening caused by hydrogen nuclei, while keeping the interaction between $^{31}\text{P}$ and the NV spin once the Hartmann–Hann condition is matched. In our numerical simulation, we apply a magnetic field $B = 290$ G such that the Larmor frequencies of $^{31}\text{P}$, $^{1}\text{H}$ and $^{13}\text{C}$ are quite different, namely equal to 500, 1235 and 310.6 kHz, respectively. The driving amplitude of the NV spin is tuned to match the effective Larmor frequency of $^{31}\text{P}$, and in the mean time its interaction with the $^{13}\text{C}$ spin bath can be effectively suppressed (see the appendix). The difference of Larmor frequencies also allow us to selectively drive the nuclei $^{1}\text{H}$ (e.g. with the driving amplitude 20 kHz) while not affecting the other two types of nuclei. The distance between the nuclei $^{31}\text{P}$ and $^{1}\text{H}$ is about 0.2 nm, and the corresponding coupling constant is $g_m \simeq 6$ kHz. The line broadening due to the hydrogen nuclei is much larger than the coupling between the NV spin and the target nucleus $^{31}\text{P}$ (which is of the order of 1 kHz at a distance of 5 nm). We remark here that shallow (below 5 nm) implantation and isotropically engineered diamond has been realized experimentally [42–45]. In figure 2(a), it can be seen that if we do not drive the nuclei $^{1}\text{H}$, the interaction between $^{31}\text{P}$ and $^{1}\text{H}$ will smear the measured signal and we can hardly get information about the position of $^{31}\text{P}$. By applying a radio frequency driving
interaction picture with respect to |a⟩ coupling is our idea. The spin state of we show that it is possible to perform (quantum non-demolition) measurement on the nuclear spin state. As nuclear spins have long coherence times and can serve as robust qubits, here resonance condition but also requires that the nuclear spin state is opposite to the NV dressed In our model of an NV spectrometer, the flip-flop process happens under the Hartmann–Hahn 4. Measurement of the single nuclear spin state

In our model of an NV spectrometer, the flip-flop process happens under the Hartmann–Hahn resonance condition but also requires that the nuclear spin state is opposite to the NV dressed spin state. As nuclear spins have long coherence times and can serve as robust qubits, here we show that it is possible to perform (quantum non-demolition) measurement on the nuclear spin state of 14N@C60 (i.e. a nitrogen atom in a C60 cage) [5, 6] as an example to demonstrate our idea. The 14N@C60 molecule has an electron spin-1/2 coupled to the 14N nuclear spin-1. The hyperfine interaction is isotropic and the spin Hamiltonian is given by

\[ H_S = \omega_e S_N^z + \omega_N I_N^z + \Delta_Q \left( I_N^z \right)^2 + a S_N \cdot I_N, \tag{12} \]

where \( \omega_e = -\gamma_e B \), \( \omega_N = \gamma_N B \) and the quadrupole splitting is \( \Delta_Q = 5.1 \text{ MHz} \), the hyperfine coupling is \( a = 15.88 \text{ MHz} \) [5, 6]. We can encode a qubit in the nuclear spin state \( |m_J = 0 \rangle \equiv |\uparrow \rangle \) and \( |m_J = +1 \rangle \equiv |\downarrow \rangle \). If the difference between the electron and nuclear Zeeman splitting \( \omega_e - \omega_N \) is large enough, the non-secular terms in the hyperfine coupling can be neglected, and thus the system Hamiltonian can be rewritten as:

\[ H_S = \omega_e S_N^z + \omega_N I_N^z + \Delta_Q \left( I_N^z \right)^2 + a S_N \cdot I_N. \tag{13} \]

When the nuclear spin is in the state of \( |m_J = 0 \rangle \), the electron spin energies are equidistant with \( \omega_e \), while for the nuclear spin state \( |m_J = +1 \rangle \), it is \( \omega_e + a \), see figure 3. By applying an additional magnetic field, the energy separation between the NV spin state \( |ms = +1 \rangle \) and \( |ms = -1 \rangle \) is

\[ \Delta = 2\omega_e, \quad \text{namely} \]

\[ H_{NV} = (\omega_0 - \omega_e) | -1 \rangle \langle -1 | + (\omega_0 + \omega_e) | +1 \rangle \langle +1 | \tag{14} \]

with \( \omega_0 = 2.87 \text{ GHz} \). This means that we will inevitably drive both NV electronic spin transitions \( |0 \rangle \leftrightarrow |\pm 1 \rangle \) if the driving amplitude \( \Omega \) is around \( \omega_e \) in order to satisfy the Hartmann–Hahn resonant condition between the NV dressed spin and the electron spin in 14N@C60, see section 2. Thus, we need to take all three sublevels of the NV spin into account. Our idea is to apply a continuous driving field at a frequency \( \omega_0 \) as

\[ H_0 = \Omega \cos(\omega_0 t) \left( |+1 \rangle \langle 0 | + |-1 \rangle \langle 0 | + \text{h.c.} \right). \tag{15} \]

The driving field is off-resonant with the NV spin transitions with the detuning \( \pm \omega_e \). In the interaction picture with respect to \( H_{NV} \), we have

\[ H_I = (2\Omega^2 + \omega_e^2)^{1/2} \left( |u \rangle \langle u | - |d \rangle \langle d | \right), \tag{16} \]

where we have three dressed states as

\[ |u \rangle = \frac{1}{\eta_+^2 + 2} \left( \eta_+^2 | -1 \rangle + 2 \eta_+ |0 \rangle + 2 |+1 \rangle \right), \tag{17} \]

\[ |D \rangle = \frac{1}{(2\Omega^2 + \omega_e^2)^{1/2}} \left( \Omega | +1 \rangle + \omega_e |0 \rangle - \Omega^{-1} | -1 \rangle \right), \tag{18} \]
Figure 3. Scheme for quantum non-demolition measurement of the nitrogen nuclear spin state in $^{14}$N@C$_{60}$ with an NV center. For the nuclear spin state $|0\rangle \equiv |m_I = 0\rangle$, the allowed electron transition frequency in $^{14}$N@C$_{60}$ is $\omega_e$ and will not be on resonance with the NV dressed spin transition frequency $\omega_{NV} = (2\Omega^2 + \omega_c^2)^{1/2}$ or $2(2\Omega^2 + \omega_c^2)^{1/2}$, while for $|1\rangle \equiv |m_I = +1\rangle$, the resonance condition is satisfied when $\omega_e + a = (2\Omega^2 + \omega_c^2)^{1/2}$.

$$|d\rangle = \frac{1}{\eta^- + 2} \left( \eta^2 | -1\rangle - 2\eta^- |0\rangle + 2 |+1\rangle \right),$$

where $\eta_{\pm} = [(2\Omega^2 + \omega_c^2)^{1/2} \pm \omega_c]/\Omega$. We note that the NV spin coupling operator $S_z$ with the other spins will induce transitions among the dressed states with two transition frequencies $\omega_1 = (2\Omega^2 + \omega_c^2)^{1/2}$ and $\omega_2 = 2(2\Omega^2 + \omega_c^2)^{1/2}$, see figure 3. Therefore, we first prepare the NV spin in the state $|D\rangle$ and then tune the Rabi frequency to be on resonance with the allowed electron transition frequency in the system $^{14}$N@C$_{60}$ corresponding to the nitrogen nuclear spin state $|m_I = +1\rangle$, namely to satisfy the following condition:

$$\omega_e + a = (2\Omega^2 + \omega_c^2)^{1/2}.$$  

After time $t$, we measure the probability that the NV spin remains in the state $|D\rangle$. If the nuclear spin is in the state $|m_I = 0\rangle$, it can be seen that the resonant condition would never be satisfied once we drive the NV spin (i.e. with $\Omega > 0$); the NV spin will thus stay in the initial state $|D\rangle$; otherwise if the nuclear spin state is $|m_I = +1\rangle$, the flip-flop process can happen and thus the state population of $|D\rangle$ will change once the resonant condition is satisfied. In figure 4(a), we see that there are actually three resonant frequencies. The splitting comes from the virtual electronic transition caused by the nuclei ($\sim a^2/\omega_e = 0.84$ MHz). In the mean time, the nuclear spin state populations are not affected by the readout procedure, and one can thus realize repetitive measurements of the nitrogen nuclear spin state $|m_I = +1\rangle$, namely to satisfy the following condition:

$$\omega_e + a = (2\Omega^2 + \omega_c^2)^{1/2}.$$ 

After time $t$, we measure the probability that the NV spin remains in the state $|D\rangle$. If the nuclear spin is in the state $|m_I = 0\rangle$, it can be seen that the resonant condition would never be satisfied once we drive the NV spin (i.e. with $\Omega > 0$); the NV spin will thus stay in the initial state $|D\rangle$; otherwise if the nuclear spin state is $|m_I = +1\rangle$, the flip-flop process can happen and thus the state population of $|D\rangle$ will change once the resonant condition is satisfied. In figure 4(a), we see that there are actually three resonant frequencies. The splitting comes from the virtual electronic transition caused by the nuclei ($\sim a^2/\omega_e = 0.84$ MHz). In the mean time, the nuclear spin state populations are not affected by the readout procedure, and one can thus realize repetitive measurements of the nitrogen nuclear spin state. Thus the readout represents a non-demolition measurement on the nuclear spin state that can be repeated. The feasibility of this idea is verified by our numerical simulation, see figures 4(b) and (c). In our
numerical simulation, we apply a magnetic field |γ_eB| = 300 MHz (namely B = 107 G), and the corresponding Larmor frequencies of ^13C and ^14N are 114.75 and 32.97 kHz, respectively. The amplitude of driving on the NV spin corresponding to the central resonant frequency \( \omega_{NV} = 316.2 \text{ MHz} \) is \( \Omega = 70.7 \text{ MHz} \), which is strong enough to suppress the effect of the ^13C spin bath. It can be seen that the required time for one readout is much shorter than the coherence time \( T_2 \) of the electron spin in ^14N@C_{60} (which is 20 \( \mu \text{s} \) at room temperature [5]) for a distance of 8 nm from ^14N@C_{60} to the NV center. We remark that if we first polarize the electron spin to the state \( | - \frac{1}{2} \rangle \) (e.g. by using the NV center), it is possible to improve the readout efficiency. We would like to also point out that the present mechanism of measuring the nuclear spin state implies that one can transfer the polarization of the NV spin to the other electron/nuclear spins, which can be exploited to achieve dynamical spin polarization.

5. Measure the spin–spin distance and alignment

For the tracking of molecular conformations or the determination of molecular structure, it can be of advantage to determine the distance between two specific external nuclei. We first consider a target system which consists of two (electron or nuclear) spins interacting with each other. The system Hamiltonian is written as

\[
H_S = -\gamma_N \mathbf{B} \cdot (\mathbf{I}_{N_1} + \mathbf{I}_{N_2}) + g \left[ \mathbf{I}_{N_1} \cdot \mathbf{I}_{N_2} - 3 (\mathbf{I}_{N_1} \cdot \hat{r}) (\mathbf{I}_{N_2} \cdot \hat{r}) \right].
\]  

The interaction strength \( g = (4\pi \hbar \mu_0 \gamma_N^2) / r^3 \) depends on the intra-distance \( r \) between two spins. The vector \( \hat{r} = r\hat{r} \) connects two spins and the unit vector \( \hat{r} \) characterizes the alignment of the spin pair. To measure their intra-distance \( r \) and the orientation of the alignment vector \( \hat{r} \), we apply a strong magnetic field \( \omega_{NV} = \gamma_N B \gg g \), as the energy spectrum will depend on the relative orientation between the alignment vector \( \hat{r} \) and the applied magnetic field. On the other hand, the NV spectrometer will thus be operating with a strong enough driving field to sufficiently

\[

\]
Figure 5. Eigenstates of two interacting spins under a strong magnetic field. We use the NV spin to detect the transition frequencies of $\Omega_1$ and $\Omega_2$, the difference between which provides information about the spin–spin coupling strength and the alignment direction of the spin pair with respect to the applied magnetic field.

decouple from the other external noise. Under such a condition, the system Hamiltonian can be rewritten as:

$$H_S = \omega_N \left( I_{N_1}^z + I_{N_2}^z \right) + g_{12} \left[ I_{N_1}^z I_{N_2}^z - \frac{1}{2} \left( I_{N_1}^x I_{N_2}^x + I_{N_1}^y I_{N_2}^y \right) \right] ,$$  \hspace{1cm} (22)

where $g_{12} = g(1 - 3 \cos^2 \theta)$, with $\cos \theta = \hat{r} \cdot \hat{b}(\theta, \phi)$, and the spin operators $I^x, I^y, I^z$ are defined in the quantization axis induced by the applied magnetic field. The eigenstates and the corresponding energies can be written as

$$|E_0\rangle = |\uparrow\uparrow\rangle , \quad E_0 = \omega_N + \frac{g}{4} \left( 1 - 3 \cos^2 \theta \right) ,$$  \hspace{1cm} (23)

$$|E_1\rangle = \sqrt{\frac{1}{2}} \left( |\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle \right) , \quad E_1 = -\frac{g}{2} \left( 1 - 3 \cos^2 \theta \right) ,$$  \hspace{1cm} (24)

$$|E_2\rangle = \sqrt{\frac{1}{2}} \left( |\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle \right) , \quad E_2 = 0 ,$$  \hspace{1cm} (25)

$$|E_3\rangle = |\downarrow\downarrow\rangle , \quad E_3 = -\omega_N + \frac{g}{4} \left( 1 - 3 \cos^2 \theta \right) .$$  \hspace{1cm} (26)

The transition from the singlet eigenstate $|E_2\rangle$ to the states $|E_0\rangle$ and $|E_3\rangle$ is determined by the inhomogeneity of the coupling operators of two spins to the NV center, namely $\hat{A}_1 - \hat{A}_2$, which is usually small if the intra-spin distance is much smaller than their distance from the NV center. Therefore, if we tune the Rabi frequency of the NV spin around the Zeeman energy $\omega_N$, the dominant flip-flop processes mainly happen with the transitions from $|E_1\rangle$ to $|E_0\rangle$ and $|E_3\rangle$, see figure 5, with the following two corresponding resonant frequencies:

$$\Omega_1 = \omega_N + \frac{3g}{4} \left( 1 - \cos^2 \theta \right) ,$$  \hspace{1cm} (27)

$$\Omega_2 = \omega_N - \frac{3g}{4} \left( 1 - \cos^2 \theta \right) .$$  \hspace{1cm} (28)
The difference between these two resonant frequencies is
\[ \Delta = \frac{3g}{2} |1 - 3 \cos^{2} \theta|, \] (29)
which provides information about the coupling strength \( g \) and the alignment vector \( \hat{r} \). To determine their exact values, we propose to apply magnetic fields in (nine) different directions, and measure the resonant frequencies, respectively, as follows:
\[ \Delta_{\hat{x}} = \frac{3g}{2} |1 - 3 r_{x}^{2}|, \] (30)
\[ \Delta_{\hat{y}} = \frac{3g}{2} |1 - 3 r_{y}^{2}|, \] (31)
\[ \Delta_{\hat{z}} = \frac{3g}{2} |1 - 3 r_{z}^{2}|, \] (32)
\[ \Delta_{\hat{x} + \hat{y}} = \frac{3g}{2} |1 - \frac{3}{2}(r_{x}^{2} + r_{y}^{2} + 2r_{x}r_{y})|, \] (33)
\[ \Delta_{\hat{x} - \hat{y}} = \frac{3g}{2} |1 - \frac{3}{2}(r_{x}^{2} + r_{y}^{2} - 2r_{x}r_{y})|, \] (34)
\[ \Delta_{\hat{x} + \hat{z}} = \frac{3g}{2} |1 - \frac{3}{2}(r_{x}^{2} + r_{z}^{2} + 2r_{x}r_{z})|, \] (35)
\[ \Delta_{\hat{x} - \hat{z}} = \frac{3g}{2} |1 - \frac{3}{2}(r_{x}^{2} + r_{z}^{2} - 2r_{x}r_{z})|, \] (36)
\[ \Delta_{\hat{y} + \hat{z}} = \frac{3g}{2} |1 - \frac{3}{2}(r_{y}^{2} + r_{z}^{2} + 2r_{y}r_{z})|, \] (37)
\[ \Delta_{\hat{y} - \hat{z}} = \frac{3g}{2} |1 - \frac{3}{2}(r_{y}^{2} + r_{z}^{2} - 2r_{y}r_{z})|. \] (38)
After some calculations, we can obtain
\[ \left[ \left( \frac{3g}{2} \right) r_{x}r_{y} \right]^{2} = \frac{(\Delta_{\hat{x} + \hat{y}}^{2} - \Delta_{\hat{x} - \hat{y}}^{2})^{2}}{36 \Delta_{\hat{x}}^{2}}, \] (39)
\[ \left[ \left( \frac{3g}{2} \right) r_{x}r_{z} \right]^{2} = \frac{(\Delta_{\hat{x} + \hat{z}}^{2} - \Delta_{\hat{x} - \hat{z}}^{2})^{2}}{36 \Delta_{\hat{z}}^{2}}, \] (40)
From equations (30)–(41), we calculate the coupling strength $g$ as

$$g^2 = \frac{2}{27} \left( \Delta_x^2 + \Delta_y^2 + \Delta_z^2 \right) + \frac{1}{27} \left[ \frac{(\Delta_{x-y}^2 - \Delta_{x+y}^2)^2}{\Delta_z^2} + \frac{(\Delta_{y-z}^2 - \Delta_{y+z}^2)^2}{\Delta_x^2} + \frac{(\Delta_{z-x}^2 - \Delta_{z+x}^2)^2}{\Delta_y^2} \right].$$

(42)

Furthermore, we obtain

$$r_x^2 = \frac{1}{3} - \frac{1}{27g^2} \left[ 4\Delta_x^2 + \frac{(\Delta_{x-y}^2 - \Delta_{x+y}^2)^2}{\Delta_z^2} + \frac{(\Delta_{y-z}^2 - \Delta_{y+z}^2)^2}{\Delta_x^2} + \frac{(\Delta_{z-x}^2 - \Delta_{z+x}^2)^2}{\Delta_y^2} \right],$$

(43)

$$r_y^2 = \frac{1}{3} - \frac{1}{27g^2} \left[ 4\Delta_y^2 + \frac{(\Delta_{x-y}^2 - \Delta_{x+y}^2)^2}{\Delta_z^2} + \frac{(\Delta_{y-z}^2 - \Delta_{y+z}^2)^2}{\Delta_x^2} + \frac{(\Delta_{z-x}^2 - \Delta_{z+x}^2)^2}{\Delta_y^2} \right],$$

(44)

$$r_z^2 = \frac{1}{3} - \frac{1}{27g^2} \left[ 4\Delta_z^2 + \frac{(\Delta_{x-y}^2 - \Delta_{x+y}^2)^2}{\Delta_z^2} + \frac{(\Delta_{y-z}^2 - \Delta_{y+z}^2)^2}{\Delta_x^2} + \frac{(\Delta_{z-x}^2 - \Delta_{z+x}^2)^2}{\Delta_y^2} \right].$$

(45)

Finally, with the obtained values of $g^2$, $r_x^2$, $r_y^2$ and $r_z^2$ we compare equations (33)–(41) with the above equations and can then decide the relative signs between $r_x$, $r_y$, $r_z$ and thereby derive the alignment vector $\hat{r}$ of the spin pair.

### 5.1. Measure the distance between two hydrogen nuclei

To demonstrate the basic principles, we have applied our ideas to the simple example of measuring the distance and alignment of two hydrogen nuclei in a water molecule, e.g. lying on the diamond surface. In figure 6, we plot the resonance frequencies with a magnetic field along different directions as in equations (30)–(38). In our numerical simulation, the strength of the magnetic field is such that $\gamma_H B = 500$ kHz (namely $B = 117$ G). The amplitude of driving on the NV spin is thus strong enough to suppress the effect of the $^{13}$C spin bath in diamond. The $^1$H$_2$O molecule is assumed to be 5 nm from the NV center, and the vector that connects two hydrogen atoms is described by $(r, \theta_0, \phi_0) = (0.1515 \text{ nm}, 118.2^\circ, 288.85^\circ)$. With the calculated resonant frequencies as shown in figure 6, we follow the equations in equations (42)–(45) and obtain that $g = 34.684$ kHz, and thereby we infer that the intramolecular distance is $d = 0.1518$ nm and the alignment direction is $(\theta, \phi) = (118.29^\circ, 288.82^\circ)$, which are in good agreement with the exact parameters of a water molecule. We remark that for different magnetic field directions, the effective flip-flop rate between the NV spin and the target system may be different. Thus, in figure 6(f), we choose a longer duration time to demonstrate a resonant dip with a depth comparable with the other magnetic directions.
5.2. Measure the distance between two organic spin labels

The protocol can be combined with spin labels and has potential applications in chemistry and biology ranging from determining the biological structure and monitoring macro-molecule motions. Spin labels are organic molecules with a stable unpaired electron [46]. They can be attached to the protein (covalent or as a ligand) via a functional group. Electron spin resonance on an ensemble based on spin labels has been widely used as a spectroscopic ruler to determine the protein structure and monitor macromolecular assembly processes. However, it is very hard to go beyond a distance of 5 nm between spin labels, because e.g. inhomogeneous line broadening limits the spatial resolution [46]. We consider the widely used nitroxide spin labels and show that the resonance linewidth (which mainly depends on the coupling strength between NV spin and spin labels) assisted by dynamical nuclear polarization and continuous drivings can be narrow enough to resolve the resonance frequency splitting for a pair of spin labels.

Figure 6. Resonance of a single $^1$H$_2$O molecule with an NV center under an additional magnetic field $\gamma_1 B = 500$ kHz (namely $B = 117$ G) in different directions: $\hat{x}$ (a), $\hat{y}$ (b), $\hat{z}$ (c), $\hat{x} + \hat{y}$ (d), $\hat{x} - \hat{y}$ (e), $\hat{x} + \hat{z}$ (f), $\hat{x} - \hat{z}$ (g), $\hat{y} + \hat{z}$ (h) and $\hat{y} - \hat{z}$ (i). The signal $S$ is measured at time $t$. In each plot, $\Delta$ denotes the distance between two resonant frequencies around the Larmor frequency as in equations (27)–(29). The $^1$H$_2$O molecule is 5 nm from the NV center, and the vector that connects two hydrogen nuclei is described by $(r, \theta_0, \phi_0) = (0.1515 \text{ nm}, 118.2^\circ, 288.85^\circ)$. From these results, we can infer that the distance is $r = 0.1518$ nm, and the alignment direction is $(\theta, \phi) = (118.29^\circ, 288.82^\circ)$ following equations (43)–(45), which are in good agreement with the exact parameters.
Figure 7. Resonance of a pair of nitroxide spin labels with a distance of \(d\). The magnetic field along the vector which connects two spin labels. A continuous driving field with a Rabi frequency of 20 MHz is applied on the spin labels. (a) The distance is \(d = 5\) nm; the coupling strength is \(g = 416.1\) kHz, which corresponds to the difference between two resonant frequencies \(\Delta_1 = \frac{3}{2}g = 624.1\) kHz. The signal is measured at time \(t = 20\) µs. (b) The distance is \(d = 8\) nm; the coupling strength is \(g = 101.6\) kHz, which corresponds to the difference between two resonant frequencies \(\Delta_1 = \frac{3}{2}g = 152.4\) kHz. The signal is measured at time \(t = 40\) µs.

with a distances larger than 5 nm, see figure 7(b) for an example of 8 nm. To suppress the effect of the nitrogen nuclear spin and enhance the signal, one can use the NV spin to first polarize the electron spin and then use the polarized electron spin to prepare the nuclear spin into the state \(|m_I = 0\rangle\). The coupling with the other nuclear spins is weak and can be suppressed by continuously driving the electron spin. If the driving amplitude is much stronger than the hyperfine coupling, the effective Hamiltonian is written as

\[
H_{NV-S} = \Omega_0 S_x + \Omega \left( S_i^x + S_i^y \right) + S_z \left( A_1 S_i^z + A_2 S_i^z \right) + g \left( 1 - 3 \cos^2 \theta \right) \left[ S_i^z S_i^z - \frac{1}{2} \left( S_i^z S_i^z + S_i^z S_i^z \right) \right],
\]

where \(\cos \theta = \hat{r} \cdot \hat{b}(\theta, \phi)\), \(S\) is the NV spin operator and \(S_i\) is the spin label operator, and the quantization axis of the spin labels are induced by the applied magnetic field. In the case when \(\Omega \gg g\), the Hamiltonian for the spin labels can be approximated as follows:

\[
H_S = \Omega \left( S_i^+ + S_i^- \right) - \frac{g}{2} \left( 1 - 3 \cos^2 \theta \right) S_i^z S_i^z + \frac{g}{8} \left( 1 - 3 \cos^2 \theta \right) \left( |\uparrow\rangle \langle \uparrow| \otimes |\downarrow\rangle \langle \downarrow| + \text{h.c.} \right),
\]

where \(|\uparrow\rangle\) and \(|\downarrow\rangle\) are the eigenstates of the spin operator \(S_i^z\). The eigenstates are similar to figure 5, and can be explicitly written as follows with the corresponding energies:

\[
|E_0\rangle = |\uparrow_x \uparrow_x\rangle, \quad E_0 = \Omega - \frac{3g}{8} \left( 1 - 3 \cos^2 \theta \right),
\]

\[
|E_1\rangle = \sqrt{\frac{1}{2}} \left( |\uparrow_x \downarrow_x\rangle + |\downarrow_x \uparrow_x\rangle \right), \quad E_1 = \frac{g}{4} \left( 1 - 3 \cos^2 \theta \right),
\]

\[
|E_2\rangle = \sqrt{\frac{1}{2}} \left( |\uparrow_x \downarrow_x\rangle - |\downarrow_x \uparrow_x\rangle \right), \quad E_2 = 0,
\]

\[
|E_3\rangle = |\downarrow_x \downarrow_x\rangle, \quad E_3 = -\Omega - \frac{3g}{8} \left( 1 - 3 \cos^2 \theta \right).
\]
The transitions from the eigenstate \(|E_1\rangle\) to the other two eigenstates \(|E_0\rangle\) and \(|E_3\rangle\) correspond to the resonant frequencies as follows:

\[ \Omega_1 = \Omega + \frac{3g}{8} (1 - 3 \cos^2 \theta), \]  
\[ \Omega_2 = \Omega - \frac{3g}{8} (1 - 3 \cos^2 \theta), \]

and the difference between these two resonant frequencies is

\[ \Delta_1 = \frac{3g}{4} |1 - 3 \cos^2 \theta|. \]

When the distance between two spin labels is large, such that the coupling operators \(A_1\) and \(A_2\) are inhomogeneous, the transition from the singlet state \(|E_2\rangle\) to the states \(|E_0\rangle\) and \(|E_3\rangle\) may also be observed (see the two less pronounced resonant peaks in figure 7) with the following resonant frequencies:

\[ \Omega_3 = \Omega + \frac{g}{8} (1 - 3 \cos^2 \theta), \]
\[ \Omega_4 = \Omega - \frac{g}{8} (1 - 3 \cos^2 \theta), \]

and the difference between these two resonant frequencies is

\[ \Delta_2 = \frac{g}{4} |1 - 3 \cos^2 \theta|. \]

5.3. Monitor the charge recombination of a radical pair

Many chemical reactions involve a radical pair intermediate, which consists of two unpaired electrons [36]. The radical pair mechanism has attracted new interest recently regarding the potential role of the quantum effect in this model to explain avian magnetoreception [47–53]. The radicals are in a charge separated state and interact with each other via exchange and dipole interactions. For a distance larger than 1 nm, the exchange interaction is negligible, and the main contribution comes from the dipole interaction. Here, we consider a simple model radical pair reaction, namely the radical pair is created in the singlet state and recombine at the same rate \(k\) for both singlet and triplet states, the dynamics of which can be described by the following master equation:

\[
\frac{d}{dt} \rho = -i[H, \rho] - \frac{1}{2} \left( L_S^\dagger L_S \rho + \rho L_S L_S^\dagger - 2 L_S \rho L_S^\dagger \right) - \frac{1}{2} \left( L_T^\dagger L_T \rho + \rho L_T L_T^\dagger - 2 L_T \rho L_T^\dagger \right),
\]

where \(H\) is the system Hamiltonian that describes the interaction between two radicals and the coupling between the NV spin and radicals when the radical pair is in the charge separated state, and the Lindblad operators \(L_S\), \(L_T\) describe the recombination of the singlet and triplet radical pair into the product state, which are written as

\[ L_S = k^{1/2} (Q_S \otimes |P\rangle \langle S|) \]
\[ L_T = k^{1/2} (Q_T \otimes |P\rangle \langle S|) \]
with $Q_s$ and $Q_T$ the projectors into the singlet and triplet subspace, and $|S\rangle$ and $|P\rangle$ represent the charge separate state and product state of the radial pair, respectively. The above master equation is equivalent to the conventional Haberkorn approach [54]. We apply the same idea as in the model of spin labels (see section 5.2) by applying an additional magnetic field and also continuously driving the radical spins to suppress the effect of the surrounding nuclei. We assume that the radical pair is created in the singlet state, so the resonant frequency near the driving Rabi frequency $\Omega_1$ is

$$\Omega_3 = \Omega + \frac{g}{8} \left( 1 - 3 \cos^2 \theta \right), \quad (57)$$

with $\cos \theta = \hat{r} \cdot \hat{b}(\theta, \phi)$ (the same as equation (51)). The charge recombination leads to the decay of the effective flip-flop rate. If the recombination rate is comparable to or smaller than the coupling between the NV spin and the radicals, it is possible to observe the resonance frequency, see an example in figure 8(a). Therefore, if we tune the Rabi frequency of the NV spin at the resonant frequency, we can monitor the recombination of the radical pairs by observing the decay of the flip-flop rate. In other words, it can serve as evidence for the charge recombination. We remark that this provides a possibility to see the chemical reaction process at a single molecule level, and may give insights into how radicals recombine into the product states.

6. Summary and outlook

We have proposed a scheme to construct a nano-scale single-molecule spectrometer based on NV centers in diamond under continuous driving. This spectrometer is tunable by changing the Rabi frequency. We demonstrate its application in the detection of a single nucleus, including its position and spin state. The idea can also be used to measure the distance and alignment of a spin pair. This opens up a novel route to determine the structure of proteins and monitor...
conformational changes and other processes of relevance to biology, chemistry and medicine. We expect that our result and its extension can greatly enrich the diamond-based quantum technologies and their applications in chemistry and biology. The implementation of the present proposal for single-molecule spectroscopy will benefit from the experimental developments including: shallow implanted NV centers in diamond [42, 43], stable microwave driving fields [34] and static magnetic fields. A practical challenge when considering the biological applications is to localize the biomolecules properly on the diamond surface and close to the NV centers. A theoretical challenge would be to calculate the resolution of the proposed microscope. That is, if we have a few atoms of the same type the efficiency of resolving them would be an interesting theoretical problem in Hamiltonian estimation, which we intend to study.

JC was also supported by a Marie-Curie Intra-European fellowship within the 7th European Community Framework Programme. We acknowledge the bwGRiD for computational resources.

Note added. After we finished preparing the manuscript, three relevant experiments were published with a demonstration of sensing distant carbon-13 nuclear spins inside diamond [55–57].

Appendix

A.1. Continuous dynamical decoupling of the $^{13}$C spin bath

The NV center spin is coupled with a $^{13}$C spin bath; the interaction is described as follows:

$$H_{NV-^{13}C} = \frac{\hbar \mu_0}{4\pi} \sum_m \frac{\gamma_m \gamma_e}{R_m^3} \left[ \mathbf{S} \cdot \mathbf{I}_m - 3 (\mathbf{S} \cdot \hat{r}) (\mathbf{I}_m \cdot \hat{r}) \right],$$  

(A.1)

Figure A.1. Decouple the NV spin from the $^{13}$C spin bath with continuous dynamical decoupling. The signal $S(t) = \langle + | \rho(t) | + \rangle$ of the NV spin as a function of time $t$. (a) In the example of $^{1}$H$_3$PO$_4$, the magnetic field is $\gamma_{^{13}}C B = 500$ kHz (i.e. $B = 290$ G, $\gamma_{^{13}}C B = 310.6$ kHz), and the driving amplitude is $\Omega = 500$ kHz. (b) In the example of $^{1}$H$_2$O, the magnetic field is $\gamma_{^{13}}C B = 500$ kHz (i.e. $B = 117$ G, $\gamma_{^{13}}C B = 125.7$ kHz), and the driving amplitude is $\Omega = 400$ kHz.
where $R_m$ is the distance from the NV center to the nuclei, and $\hat{r}$ is the unit vector that connects the NV center and nuclei. The Hamiltonian of the spin bath itself is

$$H_{13\text{C}} = -\sum_n \gamma_n \mathbf{B} \cdot \mathbf{I}_n + \frac{\hbar \mu_0}{4\pi} \sum_{n > m} \frac{\gamma_n \gamma_m}{R_{mn}^3} \left[ \mathbf{I}_m \cdot \mathbf{I}_n - 3 \left( \mathbf{I}_m \cdot \hat{r} \right) \left( \mathbf{I}_n \cdot \hat{r} \right) \right],$$

(A.2)

where $R_{mn}$ is the distance between two nuclei, and $\hat{r}$ is the unit vector that connects two nuclei.

As we want to single out the effect of the target system, we apply a continuous driving field to the NV spin which satisfies the Hatmann–Hahn condition for the target nuclear spin. Here, we use exact numerical simulation to show that continuous dynamical decoupling is very efficient for the parameters that we use for the examples in the main text, see figure A.1. Due to the computational overhead, we only consider a diamond sample with eight $^{13}\text{C}$ spins in a 4 nm sphere to demonstrate the essential idea. We remark that, in a similar way, continuous dynamical decoupling can also suppress the noise from the surface of diamond if it is due to the spins that are different from the target spin.
