Can Radiomics Analyses in $^{18}$F-FDG PET/CT Images of Primary Breast Carcinoma Predict Hormone Receptor Status?

Meme Kanserinde Primer Tümöre Ait $^{18}$F-FDG PET/BT Radiomics Parametreleri Hormon Reseptörlerini Durumunu Öngörebilir mi?

**Abstract**

**Objectives:** This study aimed to investigate the role of preoperative $^{18}$fluorine-fluorodeoxyglucose ($^{18}$F-FDG) positron emission tomography/computed tomography (PET/CT) radiomics features and metabolic parameters of primary breast tumors in predicting hormone receptor (HR) positivity.

**Methods:** A total of 153 patients with breast cancer who underwent preoperative $^{18}$F-FDG PET/CT were included. All PET/CT images were retrospectively reevaluated. Radiomics features of primary breast lesions reflecting tumor heterogeneity as well as standardized uptake value (SUV) metrics (SUV$_{\text{min}}$, SUV$_{\text{mean}}$, SUV$_{\text{max}}$, and SUV$_{\text{peak}}$) and volumetric parameters such as metabolic tumor volume and total lesion glycolysis (TLG) were extracted by commercial texture analysis software package (LIFEx; https://www.lifexsoft.org/index.php). WEKA and SPSS were used for statistical analysis. Binary logistic regression analysis was used to determine texture features predicting HR positivity. Accuracy, F-measure, precision, recall, and precision-recall curve area were used as data-mining performance criteria of texture features to predict HR positivity.

**Results:** None of the radiomics parameters were significant in predicting HR status. Only SUV metrics and TLG were statistically important. Mean ± standard deviations for SUV$_{\text{mean}}$, SUV$_{\text{max}}$, and SUV$_{\text{peak}}$ for the HR-negative group were significantly higher than those in the HR-positive group (6.73±4.36 vs. 5.20±3.32, p=0.027; 11.55±7.42 vs. 8.63±5.23, p=0.006, and 8.37±6.81 vs. 5.72±4.86; p=0.012). Cut-off values of SUV$_{\text{mean}}$, SUV$_{\text{max}}$, and SUV$_{\text{peak}}$ for the prediction of HR positivity were 4.93, 8.35, and 6.02, respectively. Among data-mining methods, logistic regression showed the best performance with accuracy of 0.762.

**Conclusion:** In addition to the relatively limited number of patients in this study, radiomics parameters cannot predict the HR status of primary breast cancer. SUV levels of the HR-negative group were significantly higher than those of the HR-positive group. To clarify the role of metabolic and radiomics parameters in predicting HR status in breast cancer, further studies involving a larger study population are needed.

Molecular Imaging and Radionuclide Therapy published by Galenos Yaynevi.
Introduction

Breast cancer is the most common cause of cancer-related deaths in women worldwide. Clinical outcome is closely related to the disease stage at diagnosis. Early diagnosis and appropriate therapy help achieve favorable outcome. However, breast cancer is a heterogeneous type of tumor with expression of several different receptors and many defined gene mutations. These characteristics at the subcellular micro level have been well investigated as molecular targets of various therapeutic approaches. Estrogen and progesterone receptor positivity is the most important prognostic factor in breast cancer. The existence and loss of hormone receptor (HR) expression have been investigated in the estimation of prognosis (1).

\[18\text{F}-\text{Fluorodeoxyglucose (18F-FDG) positron emission tomography/computed tomography (PET/CT), the most frequently used nuclear oncology method, is also recommended for staging locally advanced breast cancer, where the incidence of distant metastasis or the necessity for neoadjuvant chemotherapy is high. The use of PET radiomics in oncology has recently emerged as a new era of clinical investigation. High levels of maximum standardized uptake value (SUV}_{\text{max}}\) of the primary breast tumor have been associated with high grade and poor prognosis in breast carcinoma (2).

Radiomics is a method of extracting several features from medical images. It uses data reconstruction algorithms to obtain parameters that cannot be recognized by raw data. First-order features refer to histogram analysis based on intensity. Second-order features consider relationships between gray level values within the volume of interest (VOI) and reflect intralesion heterogeneity like gray level co-occurrence matrix and gray level run-length matrix (GLRLM). Higher-order features are obtained statistically from filtered or mathematically transformed medical images. This helps noise suppression, highlighting repetitive patterns or reveal important details (9).

These parameters have been shown to be related with some clinical or histopathological characteristics of disease, in our case, breast cancer. Further processing of these data has also provided information about the prognosis and possible beneficial therapy options (10).

Material and Methods

Patients

Ankara University Human Research Ethics Committee approval was obtained (ethical approval no: I1-43-21).

Including 32 patients who received neoadjuvant chemotherapy before primary tumor excision, 153 consecutive patients who underwent preoperative \[18\text{F}-\text{FDG PET/CT with biopsy-proven breast carcinoma in our department between July 2014 and March 2020 were included in the study. All patients underwent surgical excision of the primary tumor after \[18\text{F}-\text{FDG PET/CT. Histopathological characteristics of the excised tumor were noted including the size, Ki-67 index, estrogen receptor (ER), and progesterone receptor (PR) status of the tumor.}]

Araz et al. \[18\text{F}-\text{FDG PET/CT Radiomics in Breast Cancer Mol Imaging Radionucl Ther 2022;31:49-56}]

Bulgular: HR durumunu öngörmesinde hiçbir radiomics parametresi anlamlı bulunmadı. Sadece SUV ölçümleri ve TLG anlamlı bulundu. HR negatif grupta pozitif gruba göre nortalama SUV_{\text{esit},}\ SUV_{\text{esit},}\ SUV_{\text{esit,}}\text{ ve SUV}_{\text{esit,}}\text{ değerleri} \text{statistiksel olarak} \text{yüksek bulundu (6,73}\pm\text{4,36} 'ya karşılık} 5,20±3,32 \text{p=0,027, 11,55±7,42} 'ya karşılık) 8,63±5,23 \text{p=0,006 ve 8,37±6,81} 'ya karşılık) 5,72±4,86 \text{p=0,012). SUV}_{\text{esit,}}\text{ SUV}_{\text{esit,}}\text{ ve SUV}_{\text{esit,}}\text{ Kın HR pozitifliğini öngörmektedir. Eşik değerler sırasıyla 4,93, 8,35 ve 6,02'ydi. Veri madenciliği yöntemleri içinde lojistik regresyon 0,762 doğruluk ile en iyi performans gösterdi.}

Sonuç: Bu çalışmada kısıtlı hasta sayısı olmakla birlikte, radiomics parametreleri primer meme kanserinde HR durumunu öngöremedi. HR negatif grupta, pozitif gruba göre SUV değerleri anlamlı olarak daha yüksekti. Metabolik parametrelerin ve radiomics parametrelerinin meme kanserinde HR durumunu öngörmekedeki yerinin netleşebilmesi için daha fazla sayıda hasta içeren ilişi çalışmalara ihtiyaç vardır.

Anahtar kelimeler: Meme kanseri, PET/BT, fluorodeoksiglukoz, hormon reseptörü
The exclusion criteria were as follows: i) No significant solid lesion on CT (n=1), ii) existence of non-18F-FDG-avid tumors (n=5), iii) uncontrolled diabetes with blood glucose level >150 mg/dL (n=3), iv) multiple primary cancer (n=2), v) unavailability of details of histopathological examination data (n=10), vi) total excision of the primary tumor before 18F-FDG PET/CT (n=9), and vii) existence of primary tumor smaller than 64 voxels (n=12).

Histopathological Analysis

All cases were analyzed for ER and PR status and Ki-67 proliferation rate with immunohistochemical analysis. Immunohistochemical studies were performed with external and internal positive controls; the scattered nuclear positivity of ER and PR in normal breast ducts and acini around the tumor were used as internal positive controls. The percentage of the nuclear ER- and PR-positive invasive tumor cells was recorded. The percentage of at least 1% of the tumor cells reported as positive was recommended (11). The Ki-67 proliferation rate was counted in hotspot areas, where at least 100 tumor cells were counted, and the percentage of the nuclear Ki-67 positive tumor cells was recorded (12).

18F-FDG PET/CT Protocol

After 6 h of fasting, approximately 370 MBq 18F-FDG was injected intravenously provided that the blood glucose level was <150 mg/dL. Whole-body PET/CT images were obtained by hybrid PET/CT scanner (Discovery ST or Discovery 710, GE Medical Systems, Milwaukee, USA) from the vertex to the upper thigh 60 min after radiopharmaceutical injection. PET scan was performed 3 min/bed position. Attenuation correction was performed by low-dose CT (140 kV, 70 mA, 0.5 s/tube rotation, and slice thickness of 5 mm). Patients were allowed to breathe normally. The maximum intensity projection and attenuation-corrected PET/CT fusion images were evaluated in three planes (transaxial, coronal, and sagittal) (Advance Workstation Volumeshare 5 GE Medical Systems).

Texture and Volumetric Analysis

Whole-body PET/CT images were retrospectively reevaluated by an experienced nuclear medicine specialist (with >10 years of experience on oncological PET/CT) blinded to all histopathological and clinical data of the case. PET parameters of primary breast lesions were measured. A threshold of 40% of the SUV_max used to define the contours of semi-automated VOIs drawn around the primary tumor. Forty-two radiomics features reflecting tumor heterogeneity (first-, second-, and higher-order texture parameters) as well as SUV metrics (SUV_mean, SUV_max, and SUV_peak) and metabolic volumetric parameters such as metabolic tumor volume (MTV) and total lesion glycolysis (TLG) were extracted from the PET/CT images imported in DICOM format by the commercial texture analysis software package (LIFEx; https://www.lifexsoft.org/index.php).

VOIs on PET and CT images were identical. The resampling setup details for LIFEx were as follows: Intensity discretization with gray levels of 64 bins and intensity rescaling bound 0-20 for PET images and between -1000 and 3000 HU of gray levels of 400 bins and absolute scale bounds for CT images. The analyzed metabolic and radiomics parameters are listed in Table 1.

Statistical Analysis

WEKA 3.7 and SPSS 11.5 programs were used to evaluate the collected data. As descriptive statistics, the mean ± standard deviation and median (minimum-maximum) for quantitative variables and number and percentage of patients (percent) for qualitative variables were used. In terms of quantitative variable, a significant difference was found between the categories of the qualitative variables of HR-positive and HR-negative groups, and Mann-Whitney U test was used because the normal distribution assumptions were not met. Binary logistic regression analysis was used to determine the texture features affecting HR positivity. Receiver operating characteristic analysis was performed to determine the cut-off values for different texture features. The significance level was set as 0.05. Classification methods of support vector machine, Hoeffding tree, J48, and multilayer perceptron were used in the WEKA program. The data set was evaluated using the 10-fold cross-validation test option. Accuracy, F-measure, precision, recall, and precision-recall curve area were used as data-mining performance criteria of texture features to predict HR positivity.

Results

A total of 153 patients with locally advanced (stage IIA-III) breast cancer (150 female, 3 male, mean age 55.83±13.37 years) were enrolled. The mean tumor size was 39.92±22.83 (7-140) mm. No patients had T4 tumor (stage III B). The demographic characteristics of the patients are given in Table 2. In the final histopathological examination, tumors of 37 patients were negative for HRs. The CorrelationAttributeEval method in WEKA and binary logistic regression analysis in SPSS were used because the data set contained numerous radiomics features. By using these methods, the importance of the features and their contributions to the data set were examined. The features that were determined to be insignificant by the two methods and considered not important as clinical
information were excluded from the data set. A total of seven features remained as a result. These features were $\text{SUV}_{\text{mean}}$, $\text{SUV}_{\text{max}}$, $\text{SUV}_{\text{peak}}$, gray level zone length matrix long-zone emphasis (GLZLM LZE), TLG, MTV, and GLRLM gray level non-uniformity (GLNU). Descriptions for these features for HR-positive and HR-negative groups are shown in Table 3. The mean ± standard deviations for the $\text{SUV}_{\text{mean}}$, $\text{SUV}_{\text{max}}$, and $\text{SUV}_{\text{peak}}$ for the HR-negative group were significantly higher than that in the HR-positive group (6.73±4.36 vs. 5.20±3.32, $p=0.027$; 11.55±7.42 vs. 8.63±5.23, $p=0.006$; and 8.37±6.81 vs. 5.72±4.86, $p=0.012$). Cut-off values for the prediction of HR status for $\text{SUV}_{\text{mean}}$, $\text{SUV}_{\text{max}}$, and $\text{SUV}_{\text{peak}}$ were calculated as 4.93, 8.35, and 6.02, respectively (Table 4). Percentages of feature importance according to the HR status were given in Figure 1. When we looked at the binary logistic regression analysis results to determine the risk factors affecting HR status in addition to SUVs, TLG demonstrated significant importance (Table 5). None of the radiomics parameters were found as significant factors to predict HR status. When comparing the data-mining performance results for different methods in Table 6, logistic regression gave the best accuracy with 0.762.

**Discussion**

Staging is not the only parameter that can guide therapy in breast cancer. Intratumoral heterogeneity is a challenging issue in the management of breast cancer. Various types of genetic alterations, receptor expressions, and sensitivity to certain hormones highly affect the biological behavior and the clinical course of the disease. Classification and

prognosis estimation is thus difficult because many factors are needed to consider. Breast cancers are dependent on estrogen and progesterone for growth; thus, receptor modulators and receptor downregulators are also used in the therapeutic management of disease other than conventional chemotherapy. ER and PR positivity is known as the most important prognostic factor in breast cancer. Hormonal therapy has been shown to be beneficial in overall survival and progression-free survival (13).

Imaging at diagnosis primarily aimed to correct cancer staging. However, in heterogeneous tumors like breast cancer, tumor size, local invasion, or disease extent is not enough for prognosis estimation and treatment decision. Any radiological or functional image obtained is actually more valuable than the reconstructed image, as huge amounts of processable data are hidden. Texture analysis include the parameters derived from the first-, second-, and higher-order statistics reflecting the entropy, skewness, curtosis, etc. (14). The radiomics parameters calculated from $^{18}$F-FDG PET/CT have been reported to be related with molecular characteristics and outcome results in breast cancer (15).

SUV reflects the cellular content of the selected tumoral tissue. $SUV_{\text{max}}$ is the most widely used parameter for the absolute quantification of activity concentration of the tumoral tissue in a selected voxel in proportion to the injected activity (16). SUV calculation assumes that the injected radiopharmaceutical is evenly distributed throughout the body. Thus, it is affected by various factors such as partial volume effect, motion, time interval between injection and acquisition, and reconstruction method (16,17,18). This is why the use of volumetric parameters like MTV and TLG has been recommended, which represent the tumoral load closest to real in a given tumoral lesion. Thus, they have been advocated to be more successful in estimating disease severity in various cancers, including breast cancer (19). However, in this study, we examined PET metabolic

and radiomic features of the primary breast lesion only and investigated its relationship with the hormonal status of the tumor. All SUV parameters, including maximum, peak, and mean SUV were factors related with HR status. Interestingly, and in contrast to previously mentioned hypothesis that volumetric parameters are more reliable, MTV was not significant. However, TLG, the calculated product of MTV and SUVmean of the target lesion, was also significantly related with the HR status in patients with breast cancer. We attributed the difference between the significance level of MTV and TLG to the fact that TLG is eventually a derivative of SUV already. These results are compatible with those of a previous study (20). A study on patients with breast cancer who have undergone positron emission mammography (PEM) deserves attention because the authors presented PET data dedicated to breast. In contrast to many other studies, they proposed that volumetric data are not of significant importance and SUV is predictive of hormonal status of the tumor (4).

The dataset contains many radiomics features. Thus, according to WEKA and binary logistic regression analysis, among radiomics parameters, only GLZLM LZE and GLRLM GLNU were included. GLZLM reflects the size of the homogenous zones for each gray level in three dimensions, and LZE is the distribution of the long homogenous zones in an image. GLRLM is used for the size of homogenous runs for each gray level in three dimensions, and GLNU measures the similarity of values of the gray level. In this study, none of the radiomics parameters were significant in predicting HR status. However, previous reports on radiomics and molecular characteristics of primary breast cancer have mostly studied multiple histopathological and clinical parameters including the tumor type (ductal/lobular), tumor size, Her-2 status, Ki-67 index, and TNM stage along with the HR status. Binary logistic regression analysis and risk estimation were the primary endpoints in these studies. However, in the present study, we used data-mining method, a higher-order and more complicated statistical method than methods used in previous studies. After determining the variables indicative of HR status by binary logistic regression analysis, we created a data-mining model that can accurately select patients with positive HR status using data obtained from 18F-FDG PET/CT by utilizing the least number of features. Attempts to define quantitative features indicative of an event or characteristic of a lesion in radiological studies all serve as preliminary studies for modeling methods to be used in artificial intelligence. Studies have used various radiomics features to define HR status. However, if a program is created to determine histopathological characteristics of tumor based on 18F-FDG PET/CT study for disease staging, only a few features will be needed to create a model (21). This is why we moved one step forward in statistics compared with previous studies. We investigated the importance level of variables determined by logistic regression and generated the best model for the prediction of HR status of primary breast cancer lesions using data from 18F-FDG PET/CT performed for staging. In addition to risk estimation

PRC: Precision-recall curve
calculated by binary logistic regression, the proposed PET radiomics model including metabolic parameters can also distinguish hormone-positive from hormone-negative breast cancer with a prediction accuracy of 76%. Because data-mining methods necessitate an incredible amount of data to be processed statistically, only HR status was examined under the scope of this study.

Despite the high-level statistics conducted in a large patient population for the estimation of a very specific condition in this study, there are a few limitations necessary to mention. First, the hormone-negative group was relatively small compared with the hormone-positive group. If a greater number of patients could be included, some radiomics parameters would have been significant together with metabolic parameters. We had to exclude many patients because of faint 18F-FDG uptake and/or small breast tumors. If the same patients could be scanned with PEM or with PET/magnetic resonance (MR), some lesions may have been clarified, and these patients could have been enrolled in the study. However, PET/CT is the standard of choice in staging breast cancer because it provides data of the M status of the disease (22). PEM or PET/MR is rather used for further evaluation of local invasion or involvement of axillary lymph nodes. Radiomics data of PEM or PET/ MR would also be certainly very valuable in predicting histopathological characteristics of primary breast cancer.

**Conclusion**

In addition to the relatively limited number of patients in this study, radiomics parameters cannot predict HR status of primary breast cancer. SUV levels of the HR-negative group were significantly higher than those in the HR-positive group. To clarify the role of metabolic and radiomics parameters in predicting HR status in breast cancer, further studies with a larger number of patients are needed.
