Correspondence to: Yoshihisa Urita, Division of Gastroenterology and Hepatology, Department of Internal Medicine, Toho University School of Medicine, Omori Hospital, 6-11-1, Omori-Nishi, Ota-Ku, Tokyo 143-8541, Japan. foo@eb.mbn.or.jp

METHODS: 4139 consecutive patients (2025 men and 2114 women with a mean age of 43 years), who first attended the Outpatient Department of General Medicine and Emergency Care at Toho University Omori Hospital, were asked to respond to the F-scale questionnaire regardless of their chief complaints. The questionnaire is a self-report instrument, written in a simple and easy-to-understand language, containing 12 questions.

RESULTS: Of 4139 subjects, 1554 patients (37.6%) were identified as GERD according to their F-scale score (> 7). However, there were only 45 consultations (1.1%) for typical GERD symptoms. Although GERD symptoms are common in adults of all ages, the prevalence of GERD was highest in the 20-29 years age group and the age group 70-79 years had the lowest prevalence for both males and females.

CONCLUSION: Although there was a high rate indicating GERD in our primary care population, only 1.1% of outpatients attended our hospital with a chief complaint of GERD symptoms. Since about one-third of GERD patients are affected by atypical symptoms, general physicians need to be cautious about extrapolating these results to patients with a chief complaint other than typical GERD symptoms.

Key words: Gastroesophageal reflux disease (GERD); F-scale; Questionnaire; General practice

INTRODUCTION

Symptoms of gastro-esophageal reflux disease (GERD) are common, affecting 10%-30% of the population in Western countries[1]. Recently, the prevalence of GERD is also increasing in the Japanese population with a high prevalence of atrophic gastritis[2]. Although GERD symptoms are common in adults of all ages, the prevalence of reflux esophagitis is increasing with age, when evaluated endoscopically[3]. However, limitations in the available diagnostic tests and a bias in subjects tested may result in a lower prevalence of GERD. Since the symptoms are accompanied by endoscopic esophagitis in up to 50% of individuals with GERD[4], and endoscopy is routinely used in patients with dyspeptic symptoms in Japan, it has been difficult to diagnose GERD accurately by endoscopy. Furthermore, accurate quantitative estimates of the prevalence of GERD are difficult to obtain because GERD symptoms vary, and there has been no gold standard for the diagnosis of GERD[5,6].

Recently, a simple questionnaire (F-scale) to score GERD symptoms has been developed in Japan[7]. Results using the F-scale have been shown to correlate with endoscopic findings. Diagnosis on the basis of history is simple and noninvasive and it has been favored in general practice. The aim of this study was to accurately assess the prevalence of GERD symptoms in general practice.

MATERIALS AND METHODS

Patients

Between August 2005 and April 2006, 4139 consecutive patients (2025 men and 2114 women with a mean age of 43 years), who first attended the Outpatient Department of General Medicine and Emergency Care at Toho University Omori Hospital, were enrolled in the present study regardless of their chief complaint. Informed consent was obtained from all patients. The study was carried out in accordance with the Declaration of Helsinki, and was approved by the ethical committee at Toho University.
were identified as having GERD according to their symptoms. Among 4139 subjects, a total of 1554 patients (37.5%) scored more than 7 points, with GERD prevalence of 705 of 2025 men (35%) and 849 of 2114 women (40%). The prevalence of GERD was significantly higher in females than in males in all age groups. The significant differences in the prevalence of GERD were found between those aged 20 to 59 years and those over the age of 70 years in females (Chi-Square test, P < 0.05). The prevalence of GERD was significantly different between those aged 20 to 59 years and those over the age of 70 in males (Chi-Square test, P < 0.05).

Among the 2585 GERD-negative patients, those with points 1 to 3 were the most prevalent (959 persons, 37.1%). The proportion of patients with a score of zero points was 24.6% (635/2585) and this proportion increased with age in the older groups. The positive rate for GERD was 705 of 2025 men (35%) and 849 of 2114 women (40%). The proportion of patients with a score of zero points among GERD-negative subjects was 28.0% (1159/4139) and 7.2% (299/4139), respectively.

The positive rate for GERD was 705 of 2025 men (35%) and 849 of 2114 women (40%). Unexpectedly, the prevalence of GERD was highest in the 20-29 years age group, followed by the 30-39 years age group and the 40-49 years age group. The age group 70-79 years had the lowest prevalence for both males and females (Figure 2). The prevalence was higher in females than in males in all age groups. The significant differences in the prevalence of GERD were found between those aged 20 to 59 years and those over the age of 70 years in females (Chi-Square test, P < 0.05). The prevalence of GERD was significantly different between those aged 20 to 59 years and those over the age of 70 in males (Chi-Square test, P < 0.05).

Among the 2585 GERD-negative patients, those with points 1 to 3 were the most prevalent (959 persons, 37.1%). The proportion of patients with a score of zero points was 24.6% (635/2585) and this proportion increased with age in females, whereas in males the proportion was the lowest for both groups (Figure 3). Significant differences were found between the 60-69 years and 70-79 years age groups and the 15-19 years, 20-29 years, 30-39 years, and 40-49 years age groups in males (chi-square test, P < 0.01), and between the 20-29 years age group and the 60-69 years and 70-79 years age groups in females (Chi-Square test, P < 0.05).

As shown in Figure 4, there was no significant difference in the proportion of patients with a score of more than 9 points among GERD-positive patients for each age group. This suggests that the age distribution of GERD is unchanged if a cutoff point for diagnosing GERD is increased to 10 points. Patients with a high score of more than 10 points were found more frequently in the older age groups.
infection may result in a stomach infection, which affects both positive and negative individuals. A general population is less common in the East compared to the West. Since \( \text{H} \) \text{pylori} infection may result in hypochlorhydria, as seen in individuals with atrophic gastritis, \( \text{H} \) \text{pylori}-infected patients seem to be at lower risk of developing GERD, as is generally observed in Japan where there is a high prevalence of \( \text{H} \) \text{pylori} infection. Several reports showed an increasing trend of GERD in Asian countries in recent years. Although it has been thought that low acid secretion would be associated with a lower prevalence of GERD in the Far East, Kinoshita et al. demonstrated that gastric acid secretion in Japan is rising in both \( \text{H} \) \text{pylori}-positive and -negative individuals. Actually, decreasing prevalence of \( \text{H} \) \text{pylori} was observed in many countries as well as in Japan.

A decreasing prevalence of \( \text{H} \) \text{pylori} infection, which is positively correlated with age, may influence the age distribution of GERD. Contrary to previous reports in our study the prevalence of GERD was highest in the 20-29 years age group and decreased with age. Fujiwara et al. also reported similar findings that the prevalence of GERD symptoms was relatively higher in the 40-49 years age group and lower in the > 60 years age group. However, as reported by Wong et al., age and male sex are considered to be risk factors for heartburn and acid regurgitation even in Asia. There have been a few reports that the prevalence of endoscopic esophagitis or GERD symptoms among men reached a peak when they were in their 20s. It has been reported in Singapore, China, Argentina, Japan, USA, and Germany that middle age subjects have GERD symptoms most frequently.

For endoscopically proven erosive esophagitis, Shimazu et al. demonstrated that its prevalence was more frequent in older individuals, whereas Mishima et al. showed that there were no significant differences in age between subjects with and without erosive esophagitis. For women, the prevalence of GERD increased with age and was higher than in males in the elderly. This variability of prevalence of GERD symptoms may be explained by a heterogeneous symptom pattern. The result of questionnaires in the same patient by different physicians may lead to different conclusions. Therefore, the F-scale was self-assessed by patients in the present study. Second, the lower prevalence may be due to the term ‘heartburn’ being poorly understood by older patients. The proportion of patients with a score of zero points was 24.6% and increased with age in 15-19 years age group than other groups for both males and females (Figure 5). Significant differences were found between the 15-19 years age group and the 20-29 years, 30-39 years, 40-49 years, and 50-59 years age groups for males, and between the 15-19 years age group and the 40-49 years, 50-59 years, and 60-69 years age groups in females.

**DISCUSSION**

GERD refers to the abnormal exposure of esophageal mucosa to gastric contents. Although GERD symptoms affect 10%-30% of the population in Western countries, endoscopic esophagitis is less prevalent, and is reported to occur in up to 2% of individuals. Only one-third of GERD patients have endoscopic positive findings, while others have no obvious mucosal breaks, even though GERD symptoms are present. Furthermore, up to 50% of endoscopically diagnosed cases of reflux esophagitis present with symptoms other than heartburn or acid regurgitation. Thus, accurate diagnosis of GERD is difficult with currently accepted criteria including symptoms of heartburn and/or acid regurgitation.

Recently, it has been reported that the prevalence of endoscopic esophagitis is increasing in Japan, with most patients diagnosed as having mild esophagitis, classified into grade A and B in the Los Angeles Classification system. In addition, since the majority of Japanese GERD patients present with mild symptoms, most of them may not seek consultation with a gastroenterologist. Nandurkar et al. reported that only about half of the patients with GERD symptoms in a community seek health care over a 10-year period and only 19% of them had endoscopy. Isolauri et al. showed that medication was used by only 16% of subjects with symptoms in Norway. Based on these previous reports, it is difficult to evaluate a genuine prevalence of GERD in the Japanese population when the study is conducted in the gastroenterology unit of the hospital. Therefore, the present study was carried out in the General Medicine unit to accurately estimate prevalence of GERD symptoms in the Japanese population.

A total of 1554 patients with GERD were identified in the present study. Several population-based surveys have reported typical GERD symptoms, including heartburn and acid regurgitation, occurring at least yearly to range from 26% to 60%. These results are concordant with our findings, although GERD symptoms in the general population are less common in the East compared to the West. Since \( \text{H} \) \text{pylori} infection may result in hypochlorhydria, as seen in individuals with atrophic gastritis, \( \text{H} \) \text{pylori}-infected patients seem to be at lower risk of developing GERD, as is generally observed in Japan where there is a high prevalence of \( \text{H} \) \text{pylori} infection. Several reports showed an increasing trend of GERD in Asian countries in recent years. Although it has been thought that low acid secretion would be associated with a lower prevalence of GERD in the Far East, Kinoshita et al. demonstrated that gastric acid secretion in Japan is rising in both \( \text{H} \) \text{pylori}-positive and -negative individuals. Actually, decreasing prevalence of \( \text{H} \) \text{pylori} was observed in many countries as well as in Japan.

A decreasing prevalence of \( \text{H} \) \text{pylori} infection, which is positively correlated with age, may influence the age distribution of GERD. Contrary to previous reports in our study the prevalence of GERD was highest in the 20-29 years age group and decreased with age. Fujiwara et al. also reported similar findings that the prevalence of GERD symptoms was relatively higher in the 40-49 years age group and lower in the > 60 years age group. However, as reported by Wong et al., age and male sex are considered to be risk factors for heartburn and acid regurgitation even in Asia. There have been a few reports that the prevalence of endoscopic esophagitis or GERD symptoms among men reached a peak when they were in their 20s. It has been reported in Singapore, China, Argentina, Japan, USA, and Germany that middle age subjects have GERD symptoms most frequently.

For endoscopically proven erosive esophagitis, Shimazu et al. demonstrated that its prevalence was more frequent in older individuals, whereas Mishima et al. showed that there were no significant differences in age between subjects with and without erosive esophagitis. For women, the prevalence of GERD increased with age and was higher than in males in the elderly. This variability of prevalence of GERD symptoms may be explained by a heterogeneous symptom pattern. The result of questionnaires in the same patient by different physicians may lead to different conclusions. Therefore, the F-scale was self-assessed by patients in the present study. Second, the lower prevalence may be due to the term ‘heartburn’ being poorly understood by older patients. The proportion of patients with a score of zero points was 24.6% and increased with age in...
both males (Figure 2) and females (Figure 3) in our study. Among white American subjects, only 35% understood the meaning of heartburn, and the figure dropped to 13% for Asians living in the USA[37], although heartburn and acid regurgitation are known to be specific for GERD. Mishima et al[38] showed that only 51 of 195 patients with endoscopically proven esophagitis had GERD symptoms. This difference may be due to the vague term 'heartburn'. In addition, when the symptoms do not reach the threshold required to define 'disease', the patient may not report having heartburn. Such patients might not seek consultation with a gastroenterologist. Finally, severe esophagitis is less common in Japan[40]. Although medical attention to GERD has increased, it has not been easy for endoscopists to detect small mucosal breaks in the distal esophagus by endoscopy. Furthermore, a limitation of the endoscopic survey is that endoscopic reporting is performed by various personnel, leading to some degree of inter-observer variation with endoscopic diagnoses.

Studies that examined the influence of gender on the prevalence of GERD symptoms have found either no difference[19,22,38], female predominance[15,39,40] or male predominance[21,41]. The positive rate for GERD was 705 of 2025 men (35%) and 849 of 2114 women (40%), and the prevalence was higher in females than in males at all age groups in the present study. Although it has been well-known that a possible reason for high prevalence in elderly women is thought to be lumbar kyphosis, a similar age distribution of GERD symptoms in males and females may be due to environmental changes, including decreased prevalence of H pylori infection and atrrophic gastritis, or the Westernization of dietary and lifestyle habits.

An epidemiological study on GERD could be considered accurate only when the whole study population undergoes invasive procedures. However, this would dramatically reduce the number of participants and prejudice the response rate of the study. The F-scale, therefore, seems to be the most appropriate test for general practice patients in the management of GERD because there is no requirement of endoscopy. About 4% of the population consults a general practitioner each year because of dyspepsia[42], whereas GERD symptoms are more common in 10%-20% of the population reporting heartburn on a weekly basis in community studies[43,44]. Although increasing attention has been paid recently to the epidemiology of GERD, the lack of a standard definition and of a diagnostic gold standard may make interpretation of data more complex. In the present study, the prevalence of GERD symptoms was 37.5%, higher than previous reports in which GERD was diagnosed by the presence of single specific symptoms, such as heartburn or regurgitation. This suggests that diagnosis by key items is not sufficient to determine a person's level of GERD and that a multidimensional approach, which covers all symptom aspects, is needed. The F-scale includes two types of symptoms: one is possibly caused by gastro-esophageal reflux (#1, 4, 6, 7, 10, 12); and the other is due to dysmotility of the upper gastrointestinal tract (#2, 3, 5, 8, 9, 11). The F-scale, therefore, is thought to result in a higher prevalence of GERD.

Despite the high prevalence of GERD, most GERD is self managed, and not presented to doctors. Won et al[44] reported that 24% of GERD patients had no GERD symptoms one year after a survey and that the disappearance rate of GERD was numerically greater than the onset rate. Agreus et al[45] showed that more than half of the individuals in their study had changed their main symptom profile to either dyspepsia, irritable bowel syndrome, unspecified symptoms or were symptom-free 1-year after the first survey, although the prevalence of GERD was stable for 7 years. Actually, only 1.1% of 4139 outpatients attended our hospital with a chief complaint of GERD symptoms, despite 1554 being diagnosed as GERD by the F-scale. This indicates that most GERD symptoms do not reach the threshold required to define 'disease'. Such patients may not seek consultation with a doctor although the result of the questionnaire is positive. Since general practice registers offer the best means of sampling the general population[46], the GERD prevalence of 37.5% obtained in the present study is considered to be accurate for Japan. Furthermore, GERD symptoms are less important as the determinants of consultation in primary care than other symptoms. This is probably due to a high proportion of mild esophagitis in Japanese GERD patients.

In conclusion, GERD symptoms were highly prevalent in our primary care population. However, only 1.1% of outpatients attended our hospital with a chief complaint of GERD symptoms. Although GERD symptoms are common in adults of all ages, the prevalence of GERD was highest in the 20-29 years age group and the group aged 70-79 years had the lowest prevalence in both male and female groups. GERD is associated with organic esophageal findings, such as esophagitis and Barrett’s esophagus, but these are also present in asymptomatic individuals[47,48]. Since up to one-third of GERD patients are affected by atypical symptoms[49], general physicians need to be cautious in extrapolating these results to patients with a chief complaint other than typical GERD symptoms, such as heartburn and regurgitation.
