(Received on April 20, 2020; Revised on August 14, 2020; Accepted on August 18, 2020)

Nutrient manipulation is a promising strategy for controlling plant diseases in sustainable agriculture. Although many studies have investigated the relationships between certain elements and plant diseases, few have comprehensively explored how differing mineral nutrition levels might affect plant–fungal pathogen interactions, namely plant susceptibility and resistance. Here, we systematically explored the effects of the seven mineral elements that plants require in the greatest amounts for normal development on the susceptibility of soybean plants (*Glycine max*) to *Fusarium oxysporum* infection in controlled greenhouse conditions. Nitrogen (N) negligibly affected plant susceptibility to infection in the range 4 to 24 mM for both tested soybean cultivars. At relatively high concentrations, phosphorus (P) increased plant susceptibility to infection, which led to severely reduced shoot and root dry weights. Potassium (K), calcium (Ca), magnesium (Mg), sulfur (S), and iron (Fe) induced plant resistance to infection as their concentrations were increased. For K and Ca, moderate concentrations had a positive effect on plant resistance to the pathogen, whereas relatively high doses of either element adversely affected plant growth and promoted disease symptoms. Further experiments were conducted, assessing disease suppression by selected combinations of macro-elements and Fe at screened concentrations, i.e., K (9 mM) plus Fe (0.2 mM), and S (4 mM) plus Fe (0.2 mM). The disease index was significantly reduced by the combination of K plus Fe. In conclusion, this systematic investigation of soybean plant responses to *F. oxysporum* infection provides a solid basis for future environmentally-friendly choices for application in soybean disease control programs.

**Keywords**: *Fusarium oxysporum*, macro-element, plant yield, soybean, susceptibility

In the soybean plant (*Glycine max*), Fusarium root rot disease is caused by soil-borne fungi (*Fusarium* spp.) and is among the most frequently reported plant diseases in China (Chang et al., 2018). This fungal pathogen can affect soybean plants at any stage of development and often causes severe losses in crop yield and quality (Díaz Arias et al., 2013). The infected plants typically show poor emergence from seed and the main visible symptoms of diseased seedlings are brown or black vascular discoloration generally confined to the roots and lower stems. It was estimated that soybean yield losses due to Fusarium root rot were ca. 118.9 million USD in the United States in 2005 alone (Wrather and Koenning, 2006). In recent years, *F. oxysporum* have become the dominant pathogen responsible for soybean root rot disease in northeastern China (Li et al., 2018).

Treating seeds with fungicide is considered an effective management intervention for preventing *Fusarium* infec-
tions in commercial fields. However, in most cases, soybean farmers do not implement this practice because the benefit in yield is not worth the costs to apply it, especially as the disease incidence is somewhat weather dependent, namely more likely in cold and wet conditions (Zhang et al., 2010). Both type of cultivars grown and cultivation practices are also used to deter plant infections by *Fusarium*, but there are limited resistance resources for *Fusarium* spp. (Zhang et al., 2013). Some work also suggests beneficial microbes could be used as biocontrol agents for *Fusarium* root rot in soybean (Al-Ani et al., 2012). However, because these practices are usually labor-intensive, quite costly and not always effective, better strategies are needed to cope with this “unstable” fungal pathogen.

Mineral nutrients are vital factors for normal growth and development in plants. Yield increases for most crops are ascribed in part to their proper nutritional management. Mounting evidence also suggests that mineral elements play key roles in plant resistance to pathogens (Walters and Bingham, 2007). Plants possess preformed defenses such as cell walls, epidermal cuticles, and bark to resist pathogen attack. Plants can also activate basic defense pathways that include the production of reactive oxygen species (ROS), as well as the synthesis of antimicrobial secondary metabolites and pathogenesis-related proteins (van Loon, 2013). These defense processes are closely related to plant metabolism, which is strongly affected by nutritional status. Given the dual functioning of mineral nutrients in crop production and defense against pathogens, it should be possible to manage plant diseases by properly adjusting the contents and combinations of different essential elements.

The objectives of this study were as follows: (1) to assess the effects of seven abundant elements that plants need for normal growth (i.e., N, P, K, Ca, Mg, S, and Fe) on soybean response to *F. oxysporum*; (2) to determine the association of those effects with plant biomass production; and (3) to test selected combinations of screened concentrations of elements for disease suppression.

### Materials and Methods

**Plant material and growth conditions.** Seeds of soybean (*Glycine max* cv. DS9 and DS7) were sterilized with 75% ethanol for 3 min and then washed three times with sterile water. Two seeds were planted per pot that contained only vermiculite, which were supplemented with Hoagland basic nutrient solution (Hoagland and Arnon, 1938). The effect of vermiculite on mineral composition was explored by dipping vermiculite in water for 5 days and then the concentrations of minerals were measured (Keming, Nanjing). The results were as follows: N, 0.03 mM; P, 0.04 mM; K, 0.004 mM; Ca, 0.05 mM; Mg, 0.013 mM; S, 0.026 mM; and Fe, 0.001 mM. Compared with concentrations tested in this study, these mineral concentrations are negligible. Different nitrogen (N) concentrations were generated according to Reddy et al. (1996). For phosphorus (P), KH₂PO₄ was used to generate different P regimes. For potassium (K) and calcium (Ca), KNO₃ and Ca(NO₃)₂ were respectively adjusted to generate the corresponding concentrations. MgSO₄ was replaced with Na₂SO₄ and MgCl₂ to generate different magnesium (Mg) and sulfur (S) concentration regimes, respectively. Different concentrations of iron (Fe) were prepared as described (Fourcroy et al., 2014), for which Fe-EDTA was used. The details are listed in Supplementary Table 1. Plants were grown in a climate chamber with conditions 26°C/20°C and a 16-h/8-h light/dark cycle at 60% relative humidity.

**Fungal culture and infection assays.** *F. oxysporum* (isolated from soybean plants in the field and stored in our lab) was cultured on potato-dextrose-agar for 10 days at 25°C. The inoculation procedure followed Hoffland (Hoffland et al., 2000) with minor modifications made. In brief, spore suspensions for inoculation were prepared by flooding cultures with distilled water, then filtering them through sterile cloth. The final conidia concentration was adjusted to 10⁶ conidia/ml. Two-week-old soybean plants were used for all inoculations. Nine plants per treatment were immersed in a spore suspension for 2 h. Then the roots were washed with distilled water and put back into the pots for further growth. Two weeks after inoculation, disease severity was calculated as the percentage of root area showing any brown or black discoloration. Plant height was also measured, and the shoot dry weights and root dry weights recorded for each plant after oven drying for 24 h at 60°C.

**Data analysis.** All experiments were carried out three times. The statistical significance of disease severity differences among samples was analyzed by pairwise comparisons using Dunnett’s test. *P* < 0.05 was considered significantly different. Lower-case letters indicate results significant for soybean cv. DS9 and upper-case letters indicate results significant for soybean cv. DS7. The same method was used to analyze plant height, shoot dry weight, and root dry weight data. All statistical analyses were performed using the SPSS version 24.0 software program (IBM Corp., Armonk, NY, USA).
Results

Soybean–Fusarium interaction assays. A number of soybean cultivars were tested for their resistance to *F. oxysporum*. Different cultivars varied in their disease severity, ranging from 16% to 96% (data not shown). Soybean cv. DS9 and DS7 displayed moderate and low resistance to *F. oxysporum* respectively (Fig. 1), so they were selected for use in further experiments. For each macro-element, appropriate level was selected for normal plant growth and development.

Responses of soybean plants to N, P, and K supply. NPK fertilizer contains the most important factors contributing to crop production, so exploring their effects on plant resistance and growth parameters will have potential applications. The form of nutritional N is NO₃, and its concentration was set to a minimum of 4 mM to a maximum of 24 mM. There was no apparent effect on resistance to *F. oxysporum* in this moderate range of N concentrations. Both disease severity and plant height remained unchanged for both cultivars, but increased shoot and root dry weights were observed at higher N concentrations in cultivar DS9, whereas no effect was observed for DS7 (Fig. 2); this effect was significant at a concentration of ≥ 20 mM, whereas at ≤ 16 mM, the yield of inoculated plants was lower and similar.

The tested concentration of P ranged from 0.5 to 6 mM. High doses of P increased plant susceptibility to *F. oxysporum* in both cultivars, and this effect was significant at ≥2 mM (Fig. 3A). Accordingly, plant heights were reduced at higher P concentrations, but this impact started at a lower concentration of 1 mM (Fig. 3B). A similar pattern was also observed for shoot dry weight and root dry weight responses (Fig. 3C and D).

With more K, disease severity was reduced, but this effect was reversed at the higher concentration of 12 mM in cultivar DS9. Similar trends were also observed for shoot and root dry weights (Fig. 4). These results indicate that K
Soybean Plant Response to Fusarium

Deficiency negatively affected plant yield and resistance to *F. oxysporum*, while moderate K had positive effects on plant growth. Evidently, a high dose of K severely impacted plant growth and resistance to *F. oxysporum*.

**Responses of soybean plants to Ca, Mg, and S supply.** Ca, Mg, and S are the group of macronutrients with the second highest quantity demand in plants (Guo et al., 2015; Khan et al., 2013; Song et al., 2008). Multiple roles for these elements in plant physiology and responses to environmental challenge have been reported. In the current experimental system, moderate supply of Ca increased plant resistance to the fungal pathogen, and also plant heights and yields (Fig. 5). However, when the Ca concentration reached 12 mM, plant growth was severely inhibited in both cultivars, as evidenced by the reduced plant height, shoot dry weight, and root dry weight. Moreover, high doses of Ca also increased plant susceptibility to *F. oxysporum*. These results suggest that Ca influences both the seedling and pathogen, pointing to complex roles it may play as an important signaling molecule.

Significantly greater resistance of soybean seedlings to *F. oxysporum* was observed at an Mg concentration of 2 mM in both cultivars (Fig. 6). At this level, plant heights were also significantly improved over lower concentrations. For plant yields (shoot or root dry weight), it seems that a low level of Mg (0.5 mM) could have positive effects, and this effect was maintained up to 4 mM Mg.
High concentrations of S (either 2 or 4 mM) significantly improved plant resistance to *F. oxysporum* in both cultivars (Fig. 7). This effect was also apparent via enhanced plant height, with even a moderate amount of S able to stimulate plant height under pathogen infection. Moreover, both shoot and root dry weights were significantly improved with higher concentrations of S, with the latter more sensitive to S supply.

**Responses of soybean plants to Fe supply.** Fe is a micronutrient, but a relatively high level is required by plants compared with that for other micro-elements, so we also investigated the effects of Fe supply on plant responses to infection. Susceptibility of both cultivars to *F. oxysporum* did not change at low concentrations of Fe (0.01, 0.03, or 0.05 mM), whereas at high levels (0.1 and 0.2 mM) it was significantly decreased (Fig. 8A). At 0.1 mM Fe, disease severity was significantly decreased vis-à-vis lower concentrations. Notably, when the concentration of Fe reached 0.2 mM, an even more pronounced reduction in disease severity occurred. Accordingly, similar patterns characterized the plant height and shoot and root dry weight responses (Fig. 8B-D). These results indicate that moderate-to-high levels of Fe significantly enhance soybean resistance to *F. oxysporum* and soybean growth parameters (i.e., height, shoot and root dry weights).

**Combination of screened concentrations of elements for disease suppression.** We further tested the potential for disease suppression by combinations of elements at screened concentrations. Combinations of K (9 mM) plus Fe (0.2 mM), and S (4 mM) plus Fe (0.2 mM) were tested. The disease index was significantly reduced by the combination of K plus Fe compared with 9 mM K or 0.2 mM Fe treatments, whereas no significant difference was observed for the combination of S plus Fe compared with 4 mM S or 0.2 mM Fe (Fig. 9). This trend was observed for both cultivars.

**Discussion**

Plant fungal pathogens represent one of the major factors affecting global crop yields (van Esse et al., 2020). Planting resistant cultivars and applying fungicides are the most frequently used strategies used for controlling diseases. However, both methods have their limitations, e.g., long breeding cycles for producing resistant cultivars, rapid pathogen evolution to escape host defenses, and environmental problems caused by fungicide application (Jørgensen et
Soybean Plant Response to *Fusarium*

Macro-elements are an essential ingredient for the normal growth and development of plants, and they can substantially impact plant immune responses (Datnoff et al., 2007). While extensive studies have ascertained the effects of particular elements on plant resistance to individual pathogens (Dordas, 2008), few studies have systematically explored the relationships between macro-elements and plant responses to one or more specific fungal pathogens.

In this study, using the soybean and *F. oxysporum* interaction system, we systematically investigated the effects of the seven mineral elements that plants require in the greatest amounts for normal development on plant responses to pathogen infection. The elements had different effects on plant responses to infection in both tested soybean cultivars. N had no discernable effects on plant resistance to infection, but P increased plant susceptibility to infection, whereas K, Ca, Mg, S, and Fe each induced plant resistance to infection. These effects were corroborated by the measured plant weight, shoot and root dry weights, which are widely used indicators of plant growth status. Although both DS9 and DS7 cultivars showed similar trends in response to *F. oxysporum* infection in different nutritional conditions, they did differ in the presence of high levels of certain elements, i.e., N and K. This indicates that there are genetic factors determining the use of certain elements.

The relationship between nutrition and disease is complex, and often depends on specific pathogens and their associated hosts (Verbon et al., 2017). N, P, and K are the most commonly used fertilizers in agriculture. The role of N in disease development is somewhat contradictory, however, and the forms of nitrogen (i.e., NO₃⁻ vs. NH₄⁺) can also have different effects on diseases of plants (Mur et al., 2017). In our study, NO₃⁻ was used to test for disease resistance to *F. oxysporum* infection in different nutritional conditions, they did differ in the presence of high levels of certain elements, i.e., N and K. This indicates that there are genetic factors determining the use of certain elements.

Calcium is an important component of middle lamella and cell walls, and plays vital roles in membrane functioning and signal transduction (Thor, 2019). As such, Ca and the Ca signaling process are among the first actors involved in setting up a plant’s response to biotic interactions (Al-e, 2018). With a greater Ca concentration, soybean plants showed a trend of increased resistance; however, a high level of Ca elicited a similar response to a low level of Ca. This result indicates a complex participation of Ca in plant growth and responses to diseases. As a component of chlorophyll, Mg is essential for photosynthesis in plants. Moreover, Mg also acts as a cofactor of many enzymes, and it was reported to reduce disease severity in several crops (Guo et al., 2015; Huber and Jones, 2012). Likewise, reduced susceptibility of soybean plants to *F. oxysporum* was observed in the present study. It has long been known that applying S can control plant diseases, and both foliar- and soil-applied S was found to increase resistance of different crops to a number of pathogens (Bloem et al., 2015). In our study system, S significantly increased soybean plant resistance to *F. oxysporum*. Interestingly, compared with plant height and shoot dry weight, it was root dry weight that was more sensitive to the added S content. Although the concept of S-induced resistance has been put forward, the precise mechanisms of S operating on either side of the plant and pathogen interaction remain unknown (Bloem et al., 2015; Bollig et al., 2013). Fe is an essential nutrient for most living organisms and its role in plant-microbe interactions has been extensively studied (Aznar et al., 2015). Fe plays a dual role in this system, on the one hand catalyzing the formation of ROS that plant hosts may use to defend against pathogens, and on the other hand, possibly hastening invasion of plant tissues by necrotrophic pathogens via ROS-mediated cell death (Verbon et al., 2017). In our study, Fe significantly enhanced soybean plant resistance to *F. oxysporum*. Previous studies also showed enhanced resistance to several pathogens on Fe addition, suggesting it has potential applications in agriculture.

It is well known that nutrient deficiency can limit plant productivity, and nutrients can become toxic in excess. However, plants have developed various strategies to maintain nutrient homeostasis; thus, they are more resistant to relatively high levels of nutrients (Kehr, 2013). High levels of elements may affect plants, microbes, and their interactions. Soil microbes are sensitive to nutrient inputs (Leff et al., 2015). In this study, we tested whether ions used in large amount can have a negative effect on a pathogen. *F. oxysporum* was grown on Fusarium minimal medium (Correll et al., 1987) with selected composition of tested elements. Relatively high levels of Ca (12 mM) and S (4 mM) had significant inhibitory effects on *F. oxysporum* growth (26.11% and 34.68% respectively). For other elements, there was no significant inhibitory effect.
This result together with the observed effect of minerals on plant growth and development give us opportunities for environmentally-friendly disease control strategies in the future.

Appropriate adjustment of nutritional levels in a systematic way would not only maintain proper growth, but also enhance plant immunity and resistance to diseases. For application purposes, we selected the optimized concentrations of three elements, K, S, and Fe, to explore their combinational effects on disease suppression. For K plus Fe, a significantly reduced disease index was observed, whereas no better disease suppression effect was observed following treatment with S plus Fe compared with treatment by these elements individually. This reflects complex interactions between nutritional elements, and also elements and plant absorption. More experiments are required to understand these intricate processes.

In conclusion, the present study is, to our knowledge, the first systematic investigation of soybean plant responses to *F. oxysporum* attack under different nutrition levels of macro-elements. The results could be relevant to controlling other pathogens in soybean, and by combining such data, we hope to develop a better and friendlier nutritional management strategy for plant disease control in the future.
