The steady state properties of an interface in a stationary Couette flow are addressed within the framework of fluctuating hydrodynamics. Our study reveals that thermal fluctuations are driven out of equilibrium by an effective shear rate that differs from the applied one. In agreement with experiments, we find that the mean square displacement of the interface is strongly reduced by the flow. We also show that nonequilibrium fluctuations present a certain degree of universality in the sense that all features of the fluids can be factorized into a single control parameter. Finally, the results are discussed in the light of recent experimental and numerical studies.

I. INTRODUCTION

Soft matter systems driven far from equilibrium by a shear flow manifest striking properties as a result of their sensitivity to external fields [1]. For instance, hydrodynamics may either enhance or suppress coarsening processes [2]. Coupling with the flow can also lead to the emergence of new, shear-induced phases that are exclusively out-of-equilibrium structures [3, 4], whereas spatiotemporal oscillations and rheochaos are observed in shear-banding systems [3, 4].

Despite substantial progress, a fundamental understanding of complex fluids under shear remains a challenging question. The first reason lies in the nature of the coupling between structure and flow. Since the local structure of soft materials is readily reorganized by an external flow, it has in turn a significant impact on the flow itself. The complexity of this feedback mechanism makes that most theoretical studies are based – to a variable extent – on phenomenological models [1, 2]. The second point is that our understanding of nonequilibrium steady states (NESS) is yet far from complete. Recently, there have been several attempts to construct a unified framework to describe equilibrium and nonequilibrium phenomena [1]. In particular, fluctuations theorems [8] or extended fluctuation-dissipation relations [9] have been suggested for complex fluids under shear. But these relations still remain at the conceptual level and the link with experimental observables – power spectra, correlation functions – has not been clarified yet.

In this paper, we investigate the statistical properties of a liquid-liquid interface in a stationary flow. We argue that this system is sophisticated enough to capture the relevant features of NESS but remains simple enough to be addressed analytically. Applications of this issue might be expected for instance in microfluidics, since interfacial phenomena are inevitably enhanced as the size of the system is reduced. Still, the question of interface fluctuations under shear has received only little attention so far. From a fundamental viewpoint, equilibrium properties of liquid-liquid interfaces are now well established [10], and experimental as well as numerical studies have validated the capillary wave model down to almost molecular scales [11, 12]. This topic has experienced a renewed interest in recent years with the discovery that phase-separated colloid-polymer mixtures may have an extremely low interfacial tension [13]. Interface fluctuations can then be analyzed in real time and space using elementary video-microscopy techniques. The versatility of this method has allowed Derks and collaborators to study the statistical properties of an interface exposed to a shear flow [14]. They found that the coupling with the flow leads to a strong reduction of thermal fluctuations, while the correlation length increases. But this second point is in disagreement with recent Monte Carlo simulations of a driven Ising model [15], therefore raising the fundamental question of what features of interfaces under shear are actually universal.

Statistical fluctuations of an interface are driven by the random forces that spontaneously occur in the bulk [16]. To describe nonequilibrium properties, the main issue is thus to properly account for the coupling between the bulk and the interface. This can be achieved on the basis of fluctuating hydrodynamics (FH) [17]. Indeed, FH has been successfully applied to various NESS situations, and experimental validations have been obtained, e.g., for fluids in a temperature gradient [18]. The purpose of this paper is to apply FH to an interface under shear.

We shall proceed as follow. In Sec. II we explain how an equation of motion for the interface can be obtained from FH. We show that the distortion of capillary waves by the flow leads to a mode-coupling equation that is discussed in Sec. III. This allows us to extract NESS properties under a stationary flow in Sec. IV. In particular, we find that the fluctuations are smoothed out by the flow. The results are then discussed in Sec. V in the light of recent experimental and numerical data available in the literature. Finally, we conclude the paper with a short summary of our results. For the sake of clarity, details of the algebra are presented in Apps. A–D.

**II. HYDRODYNAMIC FORMULATION**

We first set up a hydrodynamic theory to account for the coupling between the surface and the bulk. Following the usual hypothesis of capillary wave theory, we assume the existence of an intrinsic interface separating two immiscible fluids. For moderate deformations around the $xOy$ horizontal plane, the position of the interface can be described by a single valued function $z = h(x, y, t)$. Along this article, properties of the upper (resp. lower) fluid are labeled with the subscript $i = 1$ (resp. $i = 2$). Each phase is characterized by its mass density $\rho_i$ and its viscosity $\eta_i$. We also define $\tilde{\eta} = (\eta_1 + \eta_2)/2$ the mean viscosity and $\Delta \rho = \rho_2 - \rho_1 > 0$ the mass density difference. The surface is further characterized by the interfacial tension $\sigma$ and the capillary length $l_c = \sqrt{\sigma/|\Delta \rho g|}$, with $g$ the gravitational acceleration.

The system is schematically drawn in Fig. 1. The average position of the interface is $z = 0$. It is confined between two walls, the thickness of each fluid layer being $L_1$ and $L_2$ with $L = L_1 + L_2$. A planar Couette flow is induced by moving the walls of the shear cell at constant velocity along the $x$ direction. We define $x$, $y$ and $z$ respectively as the velocity, vorticity and velocity gradient directions. Assuming that the no-slip condition applies on the walls of the cell, the fluid velocity $\mathbf{v}$ satisfies $\mathbf{v}(x, y, L_1) = V_1 \mathbf{e}_x$ and $\mathbf{v}(x, y, -L_2) = -V_2 \mathbf{e}_x$. The total shear rate is then

$$\dot{\gamma} = \frac{\dot{\gamma}_1 L_1 + \dot{\gamma}_2 L_2}{L_1 + L_2}, \quad (1)$$

where we define $\dot{\gamma}_i = V_i/L_i$ the shear rate in each phase. Without loss of generality, we assume in the following that $V_1$, $L_1$, $V_2$ and $L_2$ are chosen so that the plane of zero shear coincides with the average position of the interface. Other situations can be deduced thanks to a Galilean transformation.

For usual fluids at room temperature, thermal fluctuations occur in the overdamped regime of capillary waves. In order to describe nonequilibrium effects, the analysis is performed within the framework of fluctuating hydrodynamics $[17, 18]$. The starting point is the stochastic version of the Stokes equation

$$\eta_i \nabla^2 \mathbf{v} - \nabla p + \rho_i \mathbf{g} + \nabla \cdot \mathbf{s} = 0, \quad (2)$$

with $\mathbf{v}$ the velocity field, $p$ the pressure, and $\mathbf{g} = -g \mathbf{e}_z$. Eq. (2) is solved together with the incompressibility condition

$$\nabla \cdot \mathbf{v} = 0. \quad (3)$$

Thermal fluctuations are accounted for through the random part of the stress tensor $\mathbf{s}$. Its components $s_{\mu\nu}$ (with $\mu, \nu = x, y, z$) are stochastic forces that stem from the microscopic degrees of freedom of the fluids. Close to equilibrium their correlations are given by the fluctuation-dissipation theorem, but such a relation is not expected to hold beyond the regime of linear response. Here however, we shall take advantage of the separation of time scales between the collective modes under study – the fluctuations of the interface – and the molecular scales of the heat bath – the fluid constituents. The relaxation of an interface is characterized by the capillary time $\tau_c = 2\tilde{\eta} l_c/\sigma$; it ranges from milliseconds for usual interfaces ($\sigma \approx 10^{-2}$ mN/m) to a few seconds for ultrastiff interfaces ($\sigma \approx 10^{-10}$ mN/m). On the other hand, a particle of fluid on either side of the interface diffuses over its own diameter $a$ on a time-scale $\tau_h = \eta a^2/(k_B T)$. This time scale is at most of the order of $\tau_h \approx 10^{-3}$ s for particulate fluids with $a \approx 100$ nm $[14]$, but it is several orders of magnitude smaller for molecular fluids. Since the relevant regime considered in this work corresponds to $\dot{\gamma} \tau_c \sim 1$, the applied shear rate is too small to significantly affect the thermal motion of individual particles. In this small Peclet number limit ($\dot{\gamma} \tau_h \ll 1$), the statistics of the heat bath is not affected by the flow and we can assume that the stochastic variables have zero mean value and correlations given by $[17, 18]$

$$\langle s_{\mu\nu}(\mathbf{r}, t) s_{\mu'\nu'}(\mathbf{r}', t') \rangle = 2k_B T \eta_i (\delta_{\mu\mu'} \delta_{\nu\nu'} + \delta_{\mu\nu'} \delta_{\nu\mu'}) \times \delta(\mathbf{r} - \mathbf{r}') \delta(t - t'), \quad (4)$$

with $k_B$ the Boltzmann’s constant and $T$ the temperature.

Eqs. (2) and (3) are then solved above and below the interface, and the solutions matched with the appropriate boundary conditions. The latter have to be enforced at the instantaneous location of the interface $z = h(x, y, t)$. Explicitly, we need to express the continuity of the velocity

$$[\mathbf{v}]_h = 0, \quad (5)$$

as well as the continuity of the stress

$$[\mathbf{T}]_h \cdot \mathbf{n} = \sigma \mathbf{n} (\nabla \cdot \mathbf{n}), \quad (6)$$

FIG. 1: Schematic representation of the system. The unit vector $\mathbf{n}$ is normal to the interface and is pointing towards the upper fluid.
with the notation \( [f]_z = f(z^+) - f(z^-) \), the limit being taken respectively from above and from below. In Eq. (10), \( T = t + s \) is the total stress tensor \( \mathbf{16} \). The components of \( T \) read \( T_{\mu\nu} = -p \delta_{\mu\nu} + \eta_i (\partial_\mu v_\nu + \partial_\nu v_\mu) \), with \( \mu, \nu = x, y, \) or \( z \); the random part \( s \) is defined in Eq. (2). The unit vector \( \mathbf{n} \) is normal to the surface, pointing towards the upper fluid. It depends on the local conformation of the interface \( \mathbf{20} \)

\[
\mathbf{n} = \frac{1}{\sqrt{1 + (\nabla h)^2}} \left( -\partial_y h, -\partial_x h, 1 \right). \tag{7}
\]

Finally, once the velocity field is fully characterized, an equation of motion is obtained thanks to the kinematic relation

\[
\partial_t \mathbf{v} + \mathbf{v} \cdot \nabla \mathbf{v} = \mathbf{v}_z, \tag{8}
\]

the velocity being evaluated at \( z = h \). In this equation, the parallel components of a vector field \( \mathbf{f} = (f_x, f_y, f_z) \) are defined as \( \mathbf{f}_z = (f_x, f_y) \). For the sake of completeness, the derivation of the boundary conditions \( \mathbf{9} \) and \( \mathbf{8} \) is reminded in Appendix \( \mathbf{4} \).

III. THE INTERFACE EQUATION

It has been appreciated for a long time that interfacial fluctuations can be distorted by an external flow \( \mathbf{21, 22} \). The description of this effect requires to go beyond the linear analysis generally used to derive the dispersion relation for capillary waves. To proceed, we follow a recursive scheme that has proved its worth, e.g., in the context of polymer-membrane interactions \( \mathbf{23} \). We assume that the deformation can be written \( h(x, y, t) = \varepsilon u(x, y, t) \), with \( u(x, y, t) \sim \mathcal{O}(1) \). The dimensionless parameter that governs this small-gradient expansion is \( \varepsilon = \sqrt{k_B T / (\sigma f^2)} \). The velocity and pressure fields are then expressed as

\[
\mathbf{v} = \mathbf{v}^{(0)} + \varepsilon \mathbf{v}^{(1)} + \varepsilon^2 \mathbf{v}^{(2)} + \ldots
\]

\[
p = p^{(0)} + \varepsilon p^{(1)} + \varepsilon^2 p^{(2)} + \ldots
\]

The lowest-order term is simply the Couette flow solution for a planar interface: \( \mathbf{v}^{(0)}(r) = \gamma_1 z \mathbf{e}_z \), if \( z \geq 0 \), and \( \mathbf{v}^{(0)}(r) = \gamma_2 z \mathbf{e}_z \) if \( z \leq 0 \).

For \( n \geq 1 \), the linearity of the Stokes equation implies that each term of the series obeys Eq. (2). The coupling between successive orders originates from the boundary conditions. Indeed, the latter have to be enforced at the position of the interface. It is therefore expected that the Taylor expansion of the \( n^{th} \)-order field, when evaluated at \( z = \varepsilon u(x, y, t) \), involves contributions of all orders \( k \geq n \). To be more explicit, consider for instance the velocity field. Up to second order, it is given by

\[
\mathbf{v}(\varepsilon u) = \mathbf{v}^{(0)}(0) + \varepsilon \left[ \mathbf{v}^{(1)}(0) + u \partial_z \mathbf{v}^{(0)}(0) \right] + \varepsilon^2 \left[ \mathbf{v}^{(2)}(0) + u \partial_z \mathbf{v}^{(1)}(0) + \frac{\varepsilon^2}{2} \partial_z^2 \mathbf{v}^{(0)}(0) \right] + \ldots
\]

[Note that we have only written the \( z \)-dependence of \( \mathbf{v}(x, y, z, t) \). We proceed likewise for all fields in Eq. (3) – (8). Clearly, the Taylor expansion of the boundary conditions involves several second-order contributions, making the algebra quite cumbersome. Moreover, the study of the fluctuations requires us to solve the full three-dimensional problem. We thus defer the technical details to App. \( \mathbf{B} \) and \( \mathbf{C} \) and we now focus the discussion on the main outcomes.]

Since the problem is invariant by translation parallel to the horizontal plane, it is natural to switch to the (2D) Fourier representation \( h(q, t) = \int d^2 q \exp[-i \mathbf{q} \cdot \mathbf{r}] h(r, t) \), with \( \mathbf{r} = (x, y) \) and \( \mathbf{q} = (q_x, q_y) \). We also define the norm of the wave vector \( q = |\mathbf{q}| = (q_x^2 + q_y^2)^{1/2} \). After some algebra, we find that the relaxation of a fluctuation mode with wave vector \( \mathbf{q} \) follows a mode-coupling equation

\[
\partial_t h = -\frac{1}{\eta} h(q, t) - i \gamma_{\text{eff}} \int \frac{d^2 q'}{(2\pi)^2} k_z h(k, t) h(q - k, t)
\]

\[
+ \varphi(q, t). \tag{9}
\]

This equation constitutes the first main result of this paper. It involves a number of contributions that we now discuss. First, \( \tau_q = 4\eta q/(\sigma q^4 + L_q^2) \) is the equilibrium relaxation time of the interface. This result shows that there is no direct coupling at linear order (at least in the viscous regime). Advection of the interface by the flow takes the form of a convolution between all modes with an effective shear rate

\[
\dot{\gamma}_{\text{eff}} = \frac{\eta_1 \gamma_1 + \eta_2 \gamma_2}{\eta_1 + \eta_2}. \tag{10}
\]

Note that the second-order term does not depend on the elastic properties of the interface.

The special feature of Eqs. (9) and (10) is that the effective shear rate \( \dot{\gamma}_{\text{eff}} \) felt by the interface differs from the applied shear rate \( \dot{\gamma} \) defined in Eq. (1). Although the latter is set by the geometry of the system, the former is a dynamical quantity in the sense that it depends on the viscosities of both fluids. However, \( \dot{\gamma}_{\text{eff}} \) and \( \dot{\gamma} \) cannot be tuned independently since the continuity condition \( \mathbf{9} \) for tangential forces requires \( \eta_1 \dot{\gamma}_1 = \eta_2 \dot{\gamma}_2 \) (see App. \( \mathbf{B} \), and then

\[
\left( \frac{L_1}{\eta_1} + \frac{L_2}{\eta_2} \right) \dot{\gamma}_{\text{eff}} = \frac{L}{\eta} \dot{\gamma}. \tag{11}
\]

This relation implies that the effective shear rate can in principle be tuned in the range \( 0 \leq \dot{\gamma}_{\text{eff}} \leq 2 \dot{\gamma} \) by adjusting the experimental conditions. It is only when \( \eta_1 = \eta_2 \) that both shear rates coincide.

Thermal fluctuations are accounted for through the white noise \( \varphi(q, t) \). This contribution stems from the random part of the stress tensor (see Appendix \( \mathbf{C} \)). We find that \( \langle \varphi(q, t) \varphi(q', t') \rangle = \frac{k_B T}{2\eta q} \delta(t - t') (2\pi)^2 \delta(q + q') \). \tag{12}
Even though the system is driven far from equilibrium, there is no coupling between the noise and the external flow (at least up to $\mathcal{O}(\varepsilon^2)$) \cite{24}.

At this point, it should be mentioned that corrections similar to Eq. (3) have been suggested in the context of sheared smectic phases (see \cite{25} and references therein), or in the description of coarsening under shear \cite{26,27}.

The argument commonly invoked is the following. Since the deformation $h(x, y, t)$ is dragged along the $x$ direction by the external flow $v(0) = v(0)e_x$, the time derivative involved in the equation of motion can simply be replaced by the total derivative

$$\partial_t h \rightarrow \partial_t h + v(0)\partial_x h,$$

where $v(0)$ is evaluated at $z = h$. Of course if the slope of the velocity is continuous, i.e., if $\eta_1 = \eta_2$, there is no ambiguity: the total derivative then reads $\partial_t h + \gamma h \partial_x h$, yielding to the convolution integral in Fourier space. However, the situation is more subtle when $\eta_1 \neq \eta_2$. With the same argument, the velocity evaluated at $z = h$ would be $v(0) = \gamma h$ if $h \geq 0$, whereas it would take the value $v(0) = \gamma h$ if $h \leq 0$. Clearly, there is an inconsistency in the reasoning. The only way to remove the indeterminacy is to follow the procedure detailed in Appendix B. We emphasize in particular that the variance $\langle h^2 \rangle(x, \gamma)$ is evaluated at $\gamma = 0$ and $\alpha = 1$. In inset we show $\mathcal{I}(q_l c)$. With $\theta_q$ the angle between the direction of shear $e_x$ and the wave vector $q$. The function $\mathcal{I}(q_l c)$ depends only on the norm $q = |q|$ of the wave vector. Explicitly, we get

$$\mathcal{I}(x) = \frac{1}{\pi^2} \int d^2 s \cos \theta_q \frac{x^2_s}{|x - s| f(|x - s|)} \times \frac{|xf(x)|^{-1} - |sf(s)|^{-1}}{f(x) + f(s) + f(|x - s|)},$$

with $\theta_q$ the angle between the direction of shear $e_x$ and the wave vector $q$. The function $\mathcal{I}(q_l c)$ depends only on the norm $q = |q|$ of the wave vector. Explicitly, we get

$$\mathcal{I}(x) = \frac{1}{\pi^2} \int d^2 s \cos \theta_q \frac{x^2_s}{|x - s| f(|x - s|)} \times \frac{|xf(x)|^{-1} - |sf(s)|^{-1}}{f(x) + f(s) + f(|x - s|)},$$

with $x = |x|, s = |s|, \theta_q$, the angle between $x$ and $s$, and $f(x) = (1 + x^2)/x$. This integral cannot be evaluated analytically; the result of the numerical integration is presented in the inset of Fig. 2. \cite{28}

Eq. (15) is the second main result of this paper. It shows that the coupling is maximum in the flow direction ($\theta_q = 0$), while the spectrum is not affected in the vorticity direction ($\theta_q = \pm \frac{\pi}{2}$). As expected, the result is invariant by inversion symmetry $q_x \leftrightarrow -q_x$ or $q_q \leftrightarrow -q_q$. The correction $\Delta S(q, \gamma) = |S(q, \gamma) - S(q, 0)|$ is plotted in Fig. 2 in dimensionless units. It should be noticed that even though all the wave lengths are affected by the flow, the spectrum is mostly affected when $q \sim l^{-1}_c$. The correction then vanishes like $q^{-2}$ for larger values of $q$, whereas it scales as $\Delta S(q, \gamma) \sim q^4$ in the limit $q \rightarrow 0$.

The mean square displacement of the interface is then obtained from the sum over all modes $\langle h^2 \rangle(\gamma) = (2\pi)^{-2} \int S(q, \gamma) q dq d\theta_q$. Notice that the integral that defines the roughness at equilibrium is actually divergent. Regularization is achieved by means of a microscopic cut-off $a$ so that $\langle h^2 \rangle(0) = k_B T/(2\pi \sigma) \times \ln(l_c/a)$. In NNESS, we find that the fluctuations are strongly reduced by the external flow

$$\langle h^2 \rangle(\gamma) = \langle h^2 \rangle(0) \left[1 - K \alpha^2 + \mathcal{O}(\alpha^4) \right].$$

The correction is quadratic in the control parameter $\alpha$. In this expression, $K$ is a universal constant in the sense that it depends neither on the properties of the fluids nor of the elastic constants of the interface \cite{29}. Moreover, it is independent of the microscopic cut-off as soon as $a/l_c < 10^{-2}$. Numerically, we get $K \approx 0.087$.\n
FIG. 2: Correction to the nonequilibrium fluctuation spectrum $\Delta S(q, \gamma) = \sigma/k_B T^2 \Delta S(q, \gamma)$, in the direction of shear $\theta_q = 0$ and for $\alpha = 1$. In inset we show $\mathcal{I}(q_l c)$.\n
IV. NONEQUILIBRIUM FLUCTUATIONS

NESS properties of the interface are then extracted from the equation of motion (9) together with the noise correlations (12). Unfortunately, this class of nonlinear stochastic equation cannot be solved exactly. We are thus forced to restrict the discussion to moderate shear rates. But this does not mean that $\gamma \tau_\varepsilon$ should remain small, as might be expected from simple scaling arguments. Indeed, our study reveals that the parameter that actually governs the steady state properties of the system is the combination of the two dimensionless parameters

$$\alpha = \sqrt{\frac{k_B T}{\eta \tau_c}} \times \gamma \tau_\varepsilon \tau_c \cdot$$

Depending on experimental conditions, $\alpha$ can be small even if $\gamma \tau_\varepsilon$ is not \cite{14}. The analysis presented in the following is valid in the range $0 \leq \alpha < 1$.

Eq. (9) is solved using a perturbation theory presented in Appendix B. We first discuss the steady-state correlation function $S(q, \gamma)$ defined as

$$\lim_{t \rightarrow \infty} \langle h(q, t)h(q', t) \rangle = S(q, \gamma)(2\pi)^3 \delta(q + q') \cdot$$

It is given at equilibrium by $S(q, 0) = k_B T/(\sigma(q^2 + l_c^2))$. Under shear, the spectrum is modified according to

$$S(q, \gamma) = S(q, 0) \left[1 - \alpha^2 \mathcal{I}(q_l c) \cos^2 \theta_q + \mathcal{O}(\alpha^4) \right].$$
In this case the decay of \( C(r, \gamma) \) is slower than the equilibrium correlation function, indicating an increase of the correlation length with increasing shear rate.

Since we do not have an explicit functional form of the correlation function, it is difficult to be more quantitative regarding the correlation length. The only conclusion that can be drawn from Fig. 3 is that the decay of \( C(r, \gamma) \) at large distances is not exponential anymore. Finally note that at intermediate angles \((0 < \phi < \pi/2)\), the correlation length can be either larger or smaller than \( l_c \) depending on the shear rate.

V. DISCUSSION

Complex fluids under shear is an challenging class of nonequilibrium systems. The simple system considered in this work is a fluid interface exposed to a Couette flow. First, it was shown that the time evolution of the deformation satisfies a mode-coupling equation. Note that equations similar to Eq. (10) have been suggested in the context of soft surfaces under shear (see for instance [23, 26, 27]). As a matter of fact, it belongs to the general class of the Kardar-Parisi-Zhang equation [30] whose derivation is usually based on phenomenological grounds. Here however, Eq. (9) has been rigorously derived from hydrodynamics with no other assumption that inertial effects can be neglected. We now discuss our results in view of recent studies.

A. Comparison to experiments and simulations

We have shown that interfacial fluctuations are strongly reduced by the flow. According to Eq. (17), the reduction is governed by a universal parameter: we predict \( K \approx 0.087 \). Suppression of thermal capillary waves was indeed measured by Derks and collaborators in a recent experiment [14, 31]. This was achieved by using a phase-separated colloid-polymer mixture whose interface is characterized by a very low surface tension. The authors have used two compositions but the dynamical parameters are only available for the first sample (sample A, very close to the critical point). The thickness of the fluid layers is \( L_1 = 50 \mu m \) and \( L_2 = 350 \mu m \). Equilibrium parameters obtained from the correlation functions are \( \sigma = 2.5 \text{ nN/m}, \ l_c = 2.6 \mu m, \) and \( \tau_c = 13 \text{ s} \) [14].

The viscosities extracted from the velocity profiles are \( \eta_1 = 7.8 \text{ mPa.s} \) and \( \eta_2 = 5.2 \text{ mPa.s} \) [31]. Unfortunately, there are only two experimental points (out of 6) that correspond to the condition \( \alpha < 1 \). To fit the data for...
FIG. 4: Mean square displacement of the interface a a function of the control parameter $\alpha$. The solid circles refer to the experiment of Ref. [14] (sample A). The dotted and solid lines are the theoretical predictions of Eqs. (17) and (20), respectively, with $K_{\text{fit}} \approx 0.087$. The dashed line corresponds to the fit of Eq. (23) with $K_{\text{fit}} \approx 0.246$. The dash-dotted line is the model of Derks et al. [14].

higher values of the control parameter, we assume that Eq. (17) can be extended according to

$$\langle h^2 \rangle (\gamma) \approx \langle h^2 \rangle (0) \frac{1}{1 + K \alpha^2}. \quad (20)$$

We then perform a linear regression of the quantity $\langle h^2 \rangle (0)/\langle h^2 \rangle (\gamma)$ as a function of $\alpha^2$. We find $K_{\text{fit}} \approx 0.246$, almost 3 times the expected value. The comparison between our theoretical predictions and the experimental measurements is shown on Fig. 4. As can be seen the agreement is only qualitative, even though it is difficult to be really conclusive since most data are outside the validity range of Eq. (17) [22].

In Ref. [14], the suppression of thermal capillary waves is supported by a remarkably simple model. The authors state that only the slow modes with $\gamma q > 1$ are affected by the flow. Solving this inequality defines to two wave vectors $q_1$ and $q_2$. It is then assumed that wave vectors with $q_1 < q < q_2$ no longer contribute to the fluctuation spectrum, whereas the contribution from wave vectors outside this range is left unchanged. Their prediction of the interfacial roughness as a function of the applied shear rate $\gamma$ is in very good agreement with experimental data – see Fig. 3. Still, we argue that the hydrodynamic analysis presented in this paper provides new insights into the problem. In particular, we have shown that fluctuations are driven out of equilibrium by the effective shear rate $\gamma_{\text{eff}}$ rather than the applied shear rate $\gamma$. For sample A presented above, the ratio of effective to applied shear rate is $\gamma_{\text{eff}}/\gamma \approx 0.8$. Now, suppose that the experiment is done with the same sample composition excepted that the thicknesses of the fluid layers are inverted to $L_1 = 350 \mu m$ and $L_2 = 50 \mu m$. In this case, the ratio would be $\gamma_{\text{eff}}/\gamma \approx 1.2$: for the same value of the applied shear rate, $\alpha$ is thus expected to increase by 50 %. The ensuing difference regarding the mean square displacement should be substantial enough for the distinction between applied and effective shear rate to be experimentally observed. This would provide a direct validation of our analysis.

Finally, let us discuss the correlation functions. Our study reveals that the static structure factor is strongly modified in the flow direction, whereas fluctuation modes in the vorticity direction are not affected. This result confirms similar conclusions obtained from molecular dynamic simulations [33]. Coming back in real space, we find that the correlation length decreases in the direction of shear. This conclusion agrees with Monte Carlo simulations of a driven interface [15]. Physically, it would mean that the external flow acts as an effective potential whose strength should increase with the shear rate. However, these findings are in disagreement with the results of Derks et al. that observe an increase of the correlation length [14]. Note that experimental data are fitted using the equilibrium correlation function. This procedure is mainly based on the short distance behavior of $C(r, \gamma)$. In contrast, our conclusions are drawn from the asymptotic behaviour of the correlation function. It is thus possible that the discrepancy comes from how the correlation length is defined in practice. Other possibilities are discussed below.

B. Conjectures and future directions

The equation of motion (9) is a direct generalization of the dispersion relation for capillary waves. In particular, it is based on the same assumptions: continuum hydrodynamics and small-gradient expansion. The pertinent question is whether the apparent mismatch between theoretical predictions and experimental data can be the consequence of another mechanism [34]. In fact, several explanations are plausible.

Firstly, we remark that the diameter of the colloids is of the order of 140 nm. The capillary length is thus only ten or twenty times larger than the “microscopic” cutoff, and it is not clear whether the separation of length scales assumed to get the universal quantities ($K, I, \ldots$) is really achieved for this sample.

Secondly, Monte Carlo simulations of Smith et al. reveals that the average width of the interface is significantly reduced by the flow [15]. In the capillary wave theory, it is assumed that the density profile behaves like a step function with a strictly vanishing width. But it is known that physical parameters are directly related to the shape of the true density profile [32]. For instance, the surface tension is given by

$$\sigma = m \int dz \left( \frac{\partial \rho}{\partial z} \right)^2, \quad (21)$$

with $\rho(z, 0)$ the equilibrium profile and $m$ a constant proportional to the second moment of the intermolecular potential [35]. In the small but finite interfacial region,
density is varying rapidly so that the fluids are highly compressible. The density should therefore be modified by the flow and become a function of the applied shear rate $\rho(z, \dot{\gamma})$. A plausible consequence is that the bare surface tension might depend on $\dot{\gamma}$ as well. According to Eq. (21), the thinning of the average profile observed in [12] is expected to give rise to an increase of the surface tension, and then to an additional reduction of the fluctuations.

The latter assertion is certainly hypothetical but we argue that the measurement of the correlation function in the vorticity direction could be conclusive. Indeed, an increase of the bare surface tension would lead to an increase of $l_c$ and thus of the NESS correlation length. But a modification of $C(r, \dot{\gamma})$ arising from $\sigma(\dot{\gamma})$ is expected to be isotropic, whereas the hydrodynamic theory predicts a modification that is anisotropic. This question clearly deserves to be reconsidered both from the experimental and theoretical viewpoint.

VI. CONCLUSION

Let us briefly summarize the main results of this paper.

(i) We have generalized the hydrodynamic derivation of the dispersion relation to include the effect of an applied shear rate on the dynamics of capillary waves. Eq. (9) reveals that the system is driven out of equilibrium by an effective shear rate that differs from the applied one. The mode-coupling structure of the equation also shows that nonequilibrium fluctuations cannot be described in terms of a simple renormalization of the interfacial tension.

(ii) The analysis of the mode-coupling equation shows that the fluctuations are smoothed out by the flow, in qualitative agreement with experiments and simulations. We find that NESS fluctuations can be described in terms of a simple control parameter defined in Eq. (13). Conclusions regarding the height correlation function are more questionable. If the theory and the simulations predict a decrease of the correlation length in the direction of shear, the reverse is actually observed on the experimental side. The discrepancies might be due to the finite thickness of the interfacial region and its response to the external flow. Molecular dynamics simulations of interfaces under shear should help to clarify this point in a near future.

In conclusion, we have derived a hydrodynamic theory to account for the coupling between a shear flow and the fluctuations of an interface. Previous investigations on driven interfaces have revealed partial agreements but also significant discrepancies between experiments and numerical simulations. Although our work brings new insights into the issue, it seems that further investigations will be necessary to definitely reconcile experiment, theory and simulations. Ultimately, achievement of this program should allow to reach a deeper understanding of soft matter systems under shear.

APPENDIX A: DERIVATION OF THE BOUNDARY CONDITIONS

Since the analysis presented in this work involves nonlinear contributions, particular care has to be given to the conditions at the interface. In this appendix, we first remind the derivation of the kinematic relation Eq. (8). We then focus on the stress continuity condition Eq. (6).

1. Kinematic condition

It is convenient to represent the interface with the functional $f(x, y, z, t) = z - h(x, y, t)$. The unit vector $n$ normal to the surface is given by

$$n = \frac{\nabla f}{|\nabla f|}.$$  \hspace{1cm} (A1)

Let us focus on a point $M(x, y, z)$ that belongs to the interface. It satisfies $f(x, y, z, t) = 0$ and then

$$df = \partial_t f dt + \nabla f \cdot d\mathbf{r} = 0 .$$

If $\mathbf{w}$ is the velocity of the point $M$, the infinitesimal displacement reads $d\mathbf{r} = \mathbf{w} dt$ and therefore $\nabla f \cdot \mathbf{w} = -\partial_t f$.

Together with Eq. (A1), we then obtain

$$\mathbf{w} \cdot n = -\frac{\partial_t f}{|\nabla f|} .$$

Identifying the normal velocity of the interface $\mathbf{w} \cdot n$ with the normal velocity of the fluid $\mathbf{v} \cdot n$, one finally gets

$$\frac{\partial_t h}{\sqrt{1 + (\nabla h)^2}} = \mathbf{v} \cdot n .$$  \hspace{1cm} (A2)

Here, we have also used the fact that $\partial_t f = -\partial_t h$. This relation together with the definition (7) directly leads to Eq. (8).

2. Dynamical condition

To derive the stress condition (6), we consider an infinitesimal surface element $S$ of the interface, bound by a closed contour $\mathcal{C}$. The contour is chosen circular with radius $\epsilon$. We also define a small cylinder $\mathcal{V}$, centered on the contour $\mathcal{C}$ and with height $2\epsilon$. The forces acting on the
volume element $V$ are the body force density $f$, the tension force exerted along the perimeter $C$, and the surface force exerted by the fluids above and below the cylinder. We discuss separately each contribution.

a. Tension force

We first discuss the restoring force exerted on the contour line $C$. We assume that the contour is travelled counterclockwise. The (local) orthonormal basis associated with the line is denoted $\{m, s, n\}$, with $m$ the tangent vector, $s$ the vector normal to $C$ but tangent to $S$, and $n$ the vector normal to $S$ pointing towards the upper fluid. In this representation, the external force exerted on the contour $C$ reads

$$F_t = -\int \sigma s dl = \sigma \int (m \times n) dl = \sigma \int (dl \times n) ,$$

with $dl = m dl$. Then, according to the Stokes relation $\int dl \times A = \int (dS \times \nabla) \times A$, one gets

$$F_t = \sigma \int dS (n \times \nabla) \times n ,$$

with the surface element $dS = dS n$.

Finally, using the general identity $(A \times \nabla) \times A = \frac{1}{2} \nabla (A \cdot A) - A (\nabla \cdot A)$ and because $n \cdot n = 1$, we find

$$F_t = -\sigma \int dS (\nabla \cdot n) n . \quad (A3)$$

b. Surface force

The component $T_{\mu\nu}$ of the stress tensor $T$ corresponds the $\mu^{th}$ component of the force (per unit area) acting on a surface element normal to the direction $\nu$. In particular, the force density exerted by a fluid on a surface element with outward normal $\hat{n}$ is $T \cdot \hat{n}$.

Let us apply this definition to the elementary cylinder of volume $V$. The cylinder is sitting across the surface, the extension being $\epsilon$ on each side. Regarding the upper surface of the cylinder, the stress exerted by fluid 1 is characterized by the (outside) normal vector $\hat{n}_1 = n$ so that the force density reads $T_1 \cdot n$. Similarly on the lower surface one has $\hat{n}_2 = -n$ and the stress is $-T_2 \cdot n$. The total surface force is then

$$F_s = \int dS (T_1 - T_2) \cdot n . \quad (A4)$$

c. Force balance equation

The force balance on the volume element $V$ enclosing the surface $S$ defined by the contour $C$ then reads

$$\int_V dV \rho \frac{dv}{dt} = F_s + F_t + \int_V dV f .$$

Now if $\epsilon$ is the typical lengthscale of the volume element $V$, then the surface contributions scale as $\epsilon^2$ whereas the acceleration and the body forces scale as $\epsilon^3$. Hence in the limit $\epsilon \to 0$ the latter can be neglected and surface forces must balance. However, since the surface element is arbitrary, the integrand must vanish identically so that one finally gets the desired result

$$(T_1 - T_2) \cdot n = \sigma (\nabla \cdot n) n . \quad (A5)$$

Finally notice that the divergence of the normal vector reads in the Monge representation $20$

$$\nabla \cdot n = -\nabla^2 h + \mathcal{O}(f^3) . \quad (A6)$$

APPENDIX B: NONLINEAR RELAXATION EQUATION

The aim of this section is to derive the equation of motion $9$. The fluctuation modes of the interface are expected to be deformed by the shear flow. As we shall see, the description of this effect requires to go beyond the usual linear analysis. We focus here on the relaxation dynamics in the absence of noise. Thermal fluctuations are treated in Appendix $C$.

To begin with, we recall the Stokes equation

$$\eta \nabla^2 v - \nabla p + \rho g = 0 , \quad (B1)$$

with $g = -ge_z$ the gravitational acceleration. In the small-gradient approximation, we can express the deformation profile as $h(x, y, t) = \epsilon u(x, y, t)$ with $u(x, y, t) \sim \mathcal{O}(1)$. The dimensionless parameter that governs the small-gradient expansion is

$$\epsilon = \sqrt{\frac{k_B T}{\sigma \epsilon^2}} . \quad (B2)$$

We then assume that the fields that satisfy the Stokes equation can be expanded in powers of $\epsilon$

$$F(z) = F^{(0)}(z) + \epsilon F^{(1)}(z) + \epsilon^2 F^{(2)}(z) + \mathcal{O}(\epsilon^3) , \quad (B3)$$

where $F$ stands for $v$, $t$ or $p$. (For clarity reason, only the $z$-dependence of the fields is kept explicitly in this appendix). The solution at order $\epsilon^0$ satisfies Eq. (B1); it corresponds to the Couette flow solution for a flat interface. The other terms of the expansion (B3) are solution of the following equation

$$\eta \nabla^2 (v^{(n)}) - \nabla p^{(n)} = 0 , \quad \forall n \geq 1 . \quad (B4)$$

At order $\epsilon^1$, the solution in the absence of shear would lead to the usual dispersion relation for capillary waves. Here, the calculations are carried out up to order $\epsilon^2$.

Due to the linearity of Eq. (B4), the coupling between different orders only occurs through the boundary conditions at the interface. This suggests to use a recursive method in order to solve the problem $23$. 
1. Solution at order $\varepsilon^0$: flat interface

For a flat interface, the solution is the well-known solution for the Couette flow:

$$v^{(0)}(z) = \dot{\gamma}_1 z e_x$$
$$p^{(0)}(z) = P^{(0)} - \rho g z$$

with $i = 1$ if $z \geq 0$ and $i = 2$ if $z \leq 0$. $P^{(0)}$ is a constant. The stress tensor then reads

$$\tau^{(0)}(z) = \begin{pmatrix} -p^{(0)}(z) & 0 & \eta \dot{\gamma}_i \\ 0 & -p^{(0)}(z) & 0 \\ \eta \dot{\gamma}_i & 0 & -p^{(0)}(z) \end{pmatrix}$$

In particular, the continuity relation for the tangential stress implies $\eta \dot{\gamma}_1 = \eta \dot{\gamma}_2$.

Note that we have chosen $L_1$, $V_1$, $L_2$ and $V_2$ so that the plane of zero shear is the horizontal plane $z = 0$. At constant shear rate, any other situation can be deduced thanks to a simple Galilean transformation.

2. Solution at order $\varepsilon^1$: linear relaxation

The first-order solution satisfies Eq. (B4) with boundary conditions that involve the solution at order $\varepsilon^0$. Actually, there are two kinds of conditions that need to be enforced: continuity conditions at the interface and limit conditions far from the interface. Strictly speaking, the latter have to be expressed at the boundaries of the shear cell, $z \to L_1$ or $z \to -L_2$, where $L_1$ and $L_2$ are macroscopic lengths. In this work, we are interested on thermal fluctuations that develop on microscopic length-scales (i.e., with wavelength much smaller than $L_1$ or $L_2$). We can therefore assume that for any field $F$, the terms of the series $[B3]$ with $n \geq 1$ vanish at infinity

$$\lim_{z \to -\infty} F^{(n)}(z) = 0 \ , \ \forall n \geq 1 .$$

In the following, we first derive the boundary conditions at the interface and then solve the problem in Fourier representation.

a. Boundary conditions

To express the continuity conditions, let us define for a field $F$ the notation

$$[F]_{z_0} = F(z_0^+) - F(z_0^-)$$

with $F(z_0^\pm) = \lim_{z \to z_0^\pm} F(z)$, the limit being taken for $z \geq z_0$. The first condition that needs to be enforced is the continuity of the velocity at the interface

$$[v]_h = 0 .$$

Using the expansion $[B3]$ together with the Taylor expansion of $v(h = \varepsilon u)$, we obtain at first order

$$[v^{(1)} + u \partial_z \varepsilon^{(0)}]_0 = 0 .$$

From the result $[B5]$ we get $\partial_z v^{(0)} = \dot{\gamma}_1 e_x$, and finally

$$[u^{(1)}]_0 = (\dot{\gamma}_2 - \dot{\gamma}_1) u ,$$
$$[v^{(1)}]_0 = 0 ,$$
$$[\varepsilon^{(1)}]_0 = 0 .$$

Next, we have to enforce the condition of stress continuity Eq. (6). At first order, we obtain

$$[t^{(1)}_{\mu z} + u \partial_z t^{(0)}_{\mu z}]_0 = -\sigma \nabla^2 u \delta_{\mu z}$$

with $\mu = x, y$ or $z$. Following the result $[B7]$ for the stress tensor, we find

$$\partial_z t^{(0)}_{\mu z}(z) = \rho g \delta_{\mu z} .$$

The continuity conditions for the stress tensor then reads

$$[t^{(1)}_{xz}]_0 = 0 ,$$
$$[t^{(1)}_{yz}]_0 = 0 ,$$
$$[t^{(1)}_{zz}]_0 = \Delta \rho g u - \sigma \nabla^2 u ,$$

with $\Delta \rho = \rho_2 - \rho_1$.

b. Method and solution

The solution of the problem is expressed using the two-dimensional Fourier transform

$$\begin{cases}
F(q, z, t) = \int d^2r \exp[-iq \cdot r] F(r, z, t) , \\
F(r, z, t) = \int \frac{d^2q}{(2\pi)^2} \exp[-iq \cdot r] F(q, z, t) ,
\end{cases}$$

with $r = (x,y)$ and $q = (q_x, q_y)$. The difficulty of the algebra comes from the fact that we need to solve the full 3-dimensional problem. It then appears judicious to define a new orthogonal coordinate system that would account for the symmetries of the problem. To this aim, the vector fields are decomposed into their longitudinal, transverse and normal components $[E, F, G]$. This defines a new set of orthogonal unit vectors $(l, t, e_z)$ where $l$ is the unit vector parallel to $q$, and $t$ the in-plane vector perpendicular to $l$ and $e_z$. These vectors are expressed in the cartesian basis $(e_x, e_y, e_z)$ as

$$l = \frac{q_x}{q} e_x + \frac{q_y}{q} e_y ,$$
$$t = -\frac{q_y}{q} e_x + \frac{q_x}{q} e_y .$$
The velocity is then written as \( \mathbf{v}^{(1)} = v_t^{(1)}(1) + v_t^{(1)}(1) \mathbf{t} + v_z^{(1)}(1) \mathbf{e}_z \). Inserting this expression in Eq. \( \text{(B14)} \) leads to a system of differential equations for the Fourier-transformed quantities

\[
-\eta q^2 v_{t}^{(1)} + \eta \partial_z^2 v_{z}^{(1)} = iq\rho^{(1)}, \quad (B13a)
-\eta q^2 v_{z}^{(1)} + \eta \partial_z^2 v_{z}^{(1)} = 0, \quad (B13b)
-\eta q^2 v_{z}^{(1)} + \eta \partial_z^2 v_{z}^{(1)} = \partial_z p^{(1)}, \quad (B13c)
\]

together with the divergenceless condition

\[
 i q v_{t}^{(1)} + \partial_z v_{z}^{(1)} = 0. \quad (B14)
\]

It is not difficult to show that the solution of Eqs. \( \text{(B13)} \) and \( \text{(B14)} \) can be written

\[
v_{z}^{(1)}(z) = A_{1}^{(1)} e^{-q|z|} + B_{1}^{(1)} q e^{-q|z|}, \quad (B15a)
\]
\[
v_{t}^{(1)}(z) = C_{1}^{(1)} e^{-q|z|}, \quad (B15b)
\]
\[
p^{(1)}(z) = 2\eta \partial_z B_{1}^{(1)} q e^{-q|z|}. \quad (B15c)
\]

\( A_{1}^{(1)}, B_{1}^{(1)}, \) and \( C_{1}^{(1)} \) are the (yet undetermined) integration constants, the subscript \( i \) taking the value \( i = 1 \) if \( z \geq 0 \) and \( i = 2 \) if \( z \leq 0 \). (There should be \( a \) \text{ priori} no confusion between the subscript and the imaginary unit \( i \)). The solution for the longitudinal component follows directly from \( \text{(B14)} \). Note that the condition \( \text{(B8)} \) has already been taken into account in \( \text{(B15)} \).

Next, we have to express the boundary conditions Eqs. \( \text{(B10)} \) and \( \text{(B11)} \) in Fourier space and in the new system of coordinates. The condition \( \text{(B10c)} \) for the normal component is straightforward

\[
\left[ v_{z}^{(1)} \right]_0 = 0, \quad (B16)
\]

where of course \( v_{z}^{(1)}(q,z,t) \) now stands for the Fourier transformed quantity. Then projecting conditions \( \text{(B10a)} \) and \( \text{(B10b)} \) for the parallel components onto the directions \( \mathbf{l} \) and \( \mathbf{t} \) respectively gives

\[
\left[ v_{l}^{(1)} \right]_0 = \frac{q}{q} (\gamma_2 - \gamma_1) u, \quad (B17)
\]
\[
\left[ v_{t}^{(1)} \right]_0 = \frac{q}{q} (\gamma_1 - \gamma_2) u. \quad (B18)
\]

Regarding the continuity of the stress, the condition \( \text{(B11c)} \) is now expressed as

\[
-\partial_z^{(1)} + 2\eta \partial_z v_{z}^{(1)} = \sigma (q^2 + \ell_c^{-2}) u, \quad (B19)
\]

where we define the capillary length by \( \ell_c^2 = \sigma/(\Delta \rho g) \). Finally, the projection of \( \text{(B11a)} \) and \( \text{(B11b)} \) leads to

\[
\left[ \eta \left( \partial_z v_{t}^{(1)} + iq v_{z}^{(1)} \right) \right]_0 = 0, \quad (B20)
\]

and

\[
\left[ \eta \partial_z v_{t}^{(1)} \right]_0 = 0. \quad (B21)
\]

With the boundary conditions \( \text{(B10)} - (B21) \), we can now evaluate the 6 integration constants. We find

\[
A_{1}^{(1)} = A_{2}^{(1)} = - \frac{1}{4\eta q} \sigma (q^2 + \ell_c^{-2}) u, \quad (B22a)
\]
\[
B_{1}^{(1)} = A_{1}^{(1)} + i \frac{q}{2\eta q} \gamma_1 (\eta_2 - \eta_1) u, \quad (B22b)
\]
\[
B_{2}^{(1)} = - A_{2}^{(1)} + i \frac{q}{2\eta q} \gamma_2 (\eta_1 - \eta_2) u, \quad (B22c)
\]
\[
C_{1}^{(1)} = \frac{q}{2\eta q} \gamma_1 (\eta_2 - \eta_1) u, \quad (B22d)
\]
\[
C_{2}^{(1)} = \frac{q}{2\eta q} \gamma_2 (\eta_1 - \eta_2) u. \quad (B22e)
\]

with \( \bar{\eta} = (\eta_1 + \eta_2)/2 \).

Although the first-order solution already depends on the shear flow, it is claimed in the main body of the paper that the calculations have to be performed up to second order. To understand this point, consider the kinematic condition \( \text{(5)} \). Since \( \mathbf{v}^{(0)}(0) = 0 \), we can write at first order

\[
\partial_z h = \varepsilon v_{t}^{(1)}(0) = - \frac{1}{\tau_q} h, \quad (B23)
\]

with \( \tau_q = -1/A^{(1)} \). It appears from \( \text{(B22a)} \) that the shear rate is not involved in the equation of motion at linear order. The calculations have thus to be extended to include the first nonlinear contribution.

3. Solution at order \( \varepsilon^2 \): mode-coupling equation

a. General solution

The solution at second order satisfies the same set of linear differential equations \( \text{(B13)} \) and \( \text{(B14)} \), so that it takes the form

\[
v_{z}^{(2)}(z) = A_{1}^{(2)} e^{-q|z|} + B_{1}^{(2)} q e^{-q|z|}, \quad (B23a)
\]
\[
v_{t}^{(2)}(z) = C_{1}^{(2)} e^{-q|z|}, \quad (B23b)
\]
\[
p^{(2)}(z) = 2\eta B_{1}^{(2)} q e^{-q|z|}. \quad (B23c)
\]

Again, \( v_{t}^{(2)} \) is deduced from the incompressibility condition \( \text{(B14)} \).

It appears that not all the integration constants are needed for our purpose. Indeed, let us express the kinematic condition \( \text{(5)} \) up to second order. In direct space, it reads

\[
\varepsilon \partial_z v_{t}^{(1)} + \varepsilon^2 \partial_z u \partial_z v_{z}^{(0)}(0) + \varepsilon^2 \nabla \parallel u \cdot \mathbf{v}^{(1)}(0) = \varepsilon v_{t}^{(1)}(0) + \varepsilon^2 \partial_z v_{z}^{(1)}(0) + \varepsilon^2 v_{z}^{(2)}(0),
\]

with \( \partial_z \mathbf{v}^{(1)}(0) = \mathbf{v}^{(1)}(0) \).
where we have used the fact that \( v^{(0)}(0) = 0 \). Note that
the passage from (8) to this latter equation leads to an
indeterminacy. Indeed, although the velocity field \( \mathbf{v} \)
continuous at \( z = \hbar \), this is not the case for each term of
the expansion at \( z = 0 \). In this appendix, we thus as-
sume that the limit \( z \to 0 \) is taken from above. It can be
checked that the same results are obtained if one would
take the limit from below. We now switch to Fourier
space, where the product of two functions \( f(\mathbf{r})g(\mathbf{r}) \) is
transformed into the convolution product
\[
(f * g)(\mathbf{q}) = \int \frac{d^3k}{(2\pi)^3} f(\mathbf{k}) g(\mathbf{q} - \mathbf{k}) .
\]
We then have in Fourier representation
\[
\varepsilon \partial_t u = \varepsilon v_z^{(1)}(0) + \varepsilon^2 \left[ (u * \partial_z v_z^{(1)}(0)) - i\gamma_1 (u * q_z u) - i(v_z^{(1)}(0) * q_z u) \right] + \varepsilon^2 v_z^{(2)}(0) .
\]
With the results of the preceding section, the equation of
motion can now be written as
\[
\varepsilon \partial_t u = -\frac{1}{\tau_\eta} \varepsilon u - i\varepsilon^2 \gamma_1 (u * q_z u) \left( \frac{\eta_1 - \eta_2}{\eta} + 1 \right) + \varepsilon^2 A_1^{(2)} .
\]
Therefore, only the integration constant \( A_1^{(2)} \) is required
to get the equation of motion.

b. Integration constants

At second order, the continuity condition (5) for the
z-component of the velocity is expressed in direct space as
\[
\left[ v_z^{(2)} + u \partial_z v_z^{(1)} + \frac{u^2}{2} \partial_z^2 v_z^{(0)} \right]_0 = 0 ,
\]
leading to, in reciprocal space,
\[
\left[ v_z^{(2)} \right]_0 = i (\gamma_2 - \gamma_1) (u * q_z u) .
\]  
This relation actually involves both \( A_1^{(2)} \) and \( A_2^{(2)} \). To obtain
one equation for motion, we still need to express the normal
stress condition
\[
[\mathbf{n} \cdot \mathbf{t} \cdot \mathbf{n}]_h = -\sigma \nabla^2 h + \mathcal{O}(h^3) .
\]
Together with (B27) and (B11), it reads at order \( \varepsilon^2 \)
\[
\left[ t_z^{(2)} + u \partial_z t_z^{(1)} \right]_0 = 0 .
\]
This result is finally expressed in Fourier representation.
The derivative of the stress tensor at first order is then
obtained from Eq. (B13a)
\[
\partial_z t_z^{(1)} = -\partial_z p^{(1)} + 2\eta \partial_z^2 v_z^{(1)} = \eta \left( q^2 v_z^{(1)} + \partial_z^2 v_z^{(1)} \right) = \eta \left( q^2 v_z^{(1)} - iq \partial_z v_z^{(1)} \right) ,
\]
where we have used (C14) to get the last equality. From
the continuity relation (B20), it is not difficult to obtain the
condition
\[
\left[ t_z^{(2)} \right]_0 = 0 ,
\]
that leads to the simple relation
\[
\eta_1 A_1^{(2)} + \eta_2 A_2^{(2)} = 0 .
\]  
Inserting this result in Eq. (B20), we finally get
\[
A_1^{(2)} = i \gamma_1 (u * q_x u) \left( \frac{\eta_1 - \eta_2}{2\eta} \right) ,
\]  
\[
A_2^{(2)} = i \gamma_2 (u * q_x u) \left( \frac{\eta_2 - \eta_1}{2\eta} \right) .
\]  
If we factorize all second-order contributions in (B25),
we then arrive at the equation of motion
\[
\partial_t \varepsilon u = -\frac{1}{\tau_\eta} \varepsilon u - i \frac{2\eta_1 \gamma_1}{\eta_1 + \eta_2} (\varepsilon u * q_x \varepsilon u) .
\]
Coming back to the deformation field \( h = \varepsilon u \) and using
the fact that \( \eta_1 \gamma_1 = \eta_2 \gamma_2 \), we can write the equation of
motion in its definitive form Eq. (B).

APPENDIX C: FLUCTUATING HYDRODYNAMICS

In this appendix, we consider the Landau-Lifshitz
equation of linear fluctuating hydrodynamics (13). We
thus need to adapt the perturbative scheme developed in
Appendix B to the Stokes equation (2) including the
random part of the stress tensor \( \mathbf{s} \). To this aim, it should
be noticed that the noise correlations \( \langle s_{\mu\nu} s_{\rho\sigma}' \rangle \) given in
Eq. (4) scale as \( k_B T \) and are therefore proportional to \( \varepsilon^2 \)
[see Eq. (B2)]. From this viewpoint, the random part of
the stress tensor can be identified as a first-order contribu-
tion.

We then follow the same recursive method as in
Appendix B. There is no modification at order \( \varepsilon^0 \) and we
now discuss the first and second orders of the expan-
sion (B3).

1. Solution at order \( \varepsilon^1 \)

At first order, the stochastic version of the Stokes equation
(2) reads in the \( (\mathbf{l}, t, \mathbf{e}_z) \) basis,
\[
\eta_1 \left( \partial_t^2 - \partial_t \right) v_z^{(1)} = i q \partial_t v_z^{(1)} - i q s_z u - \partial_z s_t z ,
\]
\[
\eta_1 \left( \partial_t^2 - \partial_t \right) v_z^{(1)} = -\partial_z s_t z ,
\]
\[
\eta_1 \left( \partial_t^2 - \partial_t \right) v_z^{(1)} = \partial_z p^{(1)} - i q s_t z - \partial_z s_{zz} ,
\]
C1a, C1b, C1c together with the incompressibility condition
\[
\varepsilon v_t^{(1)} + \partial_z v_z^{(1)} = 0 .
\]  
C2
As explained in the text, the fluctuations of the random forces in the bulk are not affected by the shear flow (at least in the regime considered in this paper). The correlations are then given by the fluctuation-dissipation theorem \cite{17, 18}. In this representation, we have

\[
\langle s_{\mu\nu} s_{\mu'\nu'} \rangle = 2k_B T \eta_i (\delta_{\mu\mu'} \delta_{\nu\nu'} + \delta_{\mu\nu} \delta_{\mu'\nu'}) \\
\times (2\pi)^2 \delta (\mathbf{q} + \mathbf{q}') \delta (z - z') \delta (t - t') ,
\]

where the subscripts stand for \(l, t, o\) or \(z\).

The solution of Eqs. \((C1)\) and \((C2)\) is then obtained using the following Green’s function identity \cite{16}

\[
[\gamma^2 - q^2] \frac{1}{2q} e^{-|qz - z'|} = -\delta(z - z') .
\]

Regarding the boundary conditions, the stress tensor \(t\) in \((B10)\) and \((B11)\) now to be replaced by the total stress tensor \(T = t + s\) \cite{16, 19}. After some algebra, we obtain the evolution equation for the interface

\[
\partial_t h(\mathbf{q}, t) = -\frac{1}{\tau_q} h(\mathbf{q}, t) + \varphi(\mathbf{q}, t) ,
\]

where the noise \(\varphi(\mathbf{q}, t)\) is given by

\[
\varphi(\mathbf{q}, t) = \frac{q}{4\eta} \int_0^+ \int_0^+ dz \ e^{-qz} \left(s_{zz} - s_{ll} + 2is_{lz}\right) \\
+ \frac{q}{4\eta} \int_{-\infty}^0 \int_0^+ dz \ e^{qz} \left(s_{zz} - s_{ll} - 2is_{lz}\right) .
\]

Together with the correlations \((C3)\), we finally get the result announced in Eq. \((12)\). Note that Eq. \((C5)\) generalizes the result of Grant and Desai for a liquid-gas interface (in the absence of shear) \cite{16}.

2. Solution at order \(\epsilon^2\)

At second order, the velocity field satisfies the following set of equations

\[
\eta_i \left( \partial_t^2 - \mathbf{q}^2 \right) \epsilon_i^{(2)} = iqq^{(2)},
\]

\[
\eta_i \left( \partial_t^2 - \mathbf{q}^2 \right) \epsilon_t^{(2)} = 0 ,
\]

\[
\eta_i \left( \partial_t^2 - \mathbf{q}^2 \right) \epsilon_z^{(2)} = \partial_z p^{(2)},
\]

together with the continuity equation

\[
iqq_i^{(2)} + \partial_z \epsilon_z^{(2)} = 0 .
\]

The noise enters the problem only through the boundary conditions and the first order contribution. Again, the boundary conditions are the same as in Appendix \[\text{X}\] excepted that the stress tensor \(t\) is replaced by the total stress tensor \(T = t + s\).

The calculations are pretty lengthy so that we only give the final results. The equation of motion is obtained from the kinematic condition Eq. \([3]\). Up to second order, we find

\[
\partial_t h = -\frac{1}{\tau_q} h - i\gamma \epsilon_{\mathbf{q}^{\mathbf{q}}} \left[h * (q_z h)\right] + \varphi - \mathbf{q} \cdot \left[ \left( \mathbf{q} \phi_1 \right) * h \right] - \left( \mathbf{q} \times \left[ \left( \mathbf{q} \phi_2 \right) * h \right] \right) \cdot \mathbf{e}_z ,
\]

where \(\phi_1\) and \(\phi_2\) are defined as

\[
\phi_1(\mathbf{q}, t) = \frac{1}{4\eta q} \int_0^+ dz \ (1 - qz) e^{-qz} \left(s_{zz} - s_{ll} + 2is_{lz}\right) \\
+ \frac{1}{4\eta q} \int_{-\infty}^0 dz \ (1 + qz) e^{qz} \left(s_{zz} - s_{ll} - 2is_{lz}\right) ,
\]

and

\[
\phi_2(\mathbf{q}, t) = \frac{1}{2\eta q} \int_0^+ dz e^{-qz} \left(s_{ll} + is_{lz}\right) \\
+ \frac{1}{2\eta q} \int_{-\infty}^0 dz e^{qz} \left(s_{ll} - is_{lz}\right) .
\]

It can be noticed that the additional terms involving \(\phi_1\) and \(\phi_2\) are not induced by the external flow. At equilibrium, these second-order contributions would actually renormalize the relaxation dynamics of the interface. In non-equilibrium situation, it is argued in the next appendix that those terms do not contribute to the fluctuation spectrum at the order considered in this work. Therefore, we do not to mention them in the main document. This choice is made in order to improve the readability and to focus the discussion on the main outcomes.

APPENDIX D: SOLUTION OF THE MODE-COUPLING EQUATION

1. Linear noise

Eq. \([9]\) is solved using a perturbation theory. To this aim, let us define the time Fourier transform \(\tilde{f}(\mathbf{q}, \omega)\) of any function \(f(\mathbf{q}, t)\) as \(\tilde{f}(\mathbf{q}, \omega) = \int dt \exp(-i\omega t)f(\mathbf{q}, t)\).
The mode-coupling equation can then be rewritten
\[
\hat{h}(q, \omega) = \hat{R}_0(q, \omega) \hat{\varphi}(q, \omega) - i \gamma_{eff} \hat{R}_0(q, \omega) \times \int \frac{dk}{d^2kd\Omega} \hat{h}(k, \Omega) \hat{h}(q - k, \omega - \Omega) , \tag{D1}
\]
with \( \frac{dk}{d^2kd\Omega} = \frac{d^2k}{(2\pi)^3} \). The bare propagator \( \hat{R}(q, \omega) \) is given by
\[
\hat{R}(q, \omega) = \frac{\tau_q}{1 + i\omega\tau_q} . \tag{D2}
\]
\[
\hat{h}_q = \hat{R}_q \hat{\varphi}_q - i \gamma_{eff} \hat{R}_q \int \frac{dk}{d^2kd\Omega} \hat{R}_k \hat{R}_q - k \hat{\varphi}_q - k - \gamma_{eff} \hat{R}_q \int \frac{dk}{d^2kd\Omega} \hat{k}_k' \hat{R}_k' \hat{R}_q - k \hat{\varphi}_q - k' \hat{\varphi}_q - k' - \gamma_{eff} \hat{R}_q \int \frac{dk}{d^2kd\Omega} \hat{k}_k' \hat{R}_k' \hat{R}_q - k \hat{\varphi}_q - k' \hat{\varphi}_q - k' + O(\alpha^3) , \tag{D3}
\]
From this expansion, the evaluation of the correlation function \( \langle \hat{h}_q \hat{h}_q \rangle \) is pretty lengthy but presents no conceptual difficulty since the four-point correlation functions of the noise are given by the Wick’s theorem. The result is then Fourier-transformed back in time representation, leading to Eqs. (15) and (16).

2. Nonlinear noise

The same scheme is used to treat the nonlinear noise contributions. First, we need to specify the statistical properties of \( \phi_1 \) and \( \phi_2 \). From (C3), it is not difficult to get \( \langle \phi_1 \rangle = \langle \phi_2 \rangle = 0 \), and for \( \mu, \nu = 1 \) or 2,
\[
\langle \phi_{\mu}(q, t) \phi_{\nu}(q', t') \rangle = \frac{k_BT}{2\eta q^2} \delta(t - t') (2\pi)^2 \delta(q + q') \delta_{\mu\nu} , \tag{D4}
\]
and
\[
\langle \phi_{\mu}(q, t) \varphi(q', t) \rangle = 0 . \tag{D5}
\]
The solution of the problem is then obtained as the solution of a Dyson equation. The calculations are performed up to second order in the small parameter \( \alpha \) (which is proportional to \( \gamma_{eff} \)). Using the shorthand notation \( \hat{h}_q = \hat{h}(q, \omega) \), we get

The solution is then expressed as a Dyson equation similar to Eq. (D3). Although the expression of \( \hat{h}_q \) involves more terms, it can be shown that most of the additional contributions to \( \langle \hat{h}_q \hat{h}_q \rangle \) actually vanish (either because they involve an odd number of noise terms, or because of the vanishing cross-correlations between \( \varphi, \phi_1 \) and \( \phi_2 \)). As a matter of fact, additional shear-induced contributions are at least of order \( \varepsilon^6 \), and thus do not contribute to the modification of the spectrum at the order considered in this work.

Still, the nonlinear noise does give rise to non-vanishing contributions at order \( \varepsilon^4 \). But those terms are equilibrium contributions since they do not involve the shear rate. Consider for instance the mean square displacement: those terms would simply renormalize the equilibrium value \( \langle h^2 \rangle(0) \). This is why we have carefully plotted the ratio \( \langle h^2 \rangle(\gamma)/\langle h^2 \rangle(0) \), that represents the modification of the fluctuations by the shear with respect to the equilibrium situation [8].

[24] As a matter of fact, our analysis reveals that convolutions between deformation and noise of the form
\[ \int dq' h(q', t) s_{\mu\nu}(q - q', t) \ldots \] also occur in the equation of motion (see Appendix C). These nonlinear terms are not coupled to the flow. At equilibrium, they would actually renormalize the relaxation dynamics of the interface. However, it is explained in Appendix D that they do not contribute to the fluctuation spectrum at order \( \varepsilon^4 \), so that they will not be considered in the following.
