Abstract

Baker and Norine introduced a graph-theoretic analogue of the Riemann-Roch theory. A central notion in this theory is the rank of a divisor. In this paper we prove that computing the rank of a divisor on a graph is \textbf{NP}-hard.

The determination of the rank of a divisor can be translated to a question about a chip-firing game on the same underlying graph. We prove the \textbf{NP}-hardness of this question by relating chip-firing on directed and undirected graphs.

Keywords: chip-firing game, Riemann-Roch theory, computational complexity, Eulerian graph

2010 MSC: 05C57, 05C45, 14H55

1. Introduction

The Riemann-Roch theory for graphs was introduced by Baker and Norine\footnote{Partially supported by the Hungarian Scientific Foundation grants no. 104178 and 105645.} in 2007 as the discrete analogue of the Riemann-Roch theory for Riemann surfaces. They defined the notions divisor, linear equivalence, rank, gonality, also in this combinatorial setting, and showed that the analogue of basic theorems as for example the Riemann-Roch theorem, remains true.

Theorems like Baker’s specialization lemma\footnote{Partially supported by the Hungarian Scientific Foundation grant no. K 109240.} or a theorem of Hladký, Král’ and Norine\footnote{Partially supported by the Hungarian Scientific Foundation grants no. 104178 and 105645.} establish a connection between the rank of a divisor on a graph and on a curve, which enables a rich interaction of the discrete and continuous theories.

A central notion in the Riemann-Roch theory is the rank of a divisor. The question whether the rank can be computed in polynomial time was posed by...
Hladký, Král’ and Norine in [5], attributing the question to H. Lenstra. In the same paper the authors gave a finite algorithm for computing the rank of a divisor on a metric graph. Manjunath [6] gave an algorithm for computing the rank of a divisor on a graph (possibly with multiple edges), that runs in polynomial time if the number of vertices of the graph is a constant.

Our main goal in this paper is to show that computing the rank of a divisor on a graph is **NP**-hard. This result implies also the **NP**-hardness of computing the rank of a divisor on a tropical curve by [5, Theorem 3]. We also show that for divisors on graphs that are in a sense “large”, the rank is a simple function of the degree of the divisor and the number of vertices and edges of the graph, therefore it can be computed in polynomial time.

Our method is the following: We translate the question of computing the rank of a divisor to a question about the chip-firing game of Björner, Lovász and Shor using the duality between these frameworks discovered by Baker and Norine [2]. We get that the following question is computationally equivalent to the determination of the rank: Given an initial chip-distribution on an (undirected) graph $G$, what is the minimum number of extra chips we need to put on this distribution to make the game infinite.

We first prove the **NP**-hardness of computing the minimum number of chips that enables an infinite game on an Eulerian digraph by showing that it equals to the number of arcs in a minimum cardinality feedback arc set. Recently, Perrot and Pham [7] solved an analogous question in the abelian sandpile model (which is a closely related variant of the chip-firing game). Our result follows by applying their method to the chip-firing game.

Then we show that the second question (concerning chip-firing games on directed graphs) can be reduced to the first one (concerning undirected graphs). In order to do so, we assign an undirected graph and an initial distribution to any Eulerian digraph such that in the short run, chip-firing on the undirected graph imitates chip-firing on the digraph.

2. Preliminaries

2.1. Basic notations

Throughout this paper, graph means a connected undirected graph that can have multiple edges but no loops. A graph is simple if it does not have multiple edges. A graph is usually denoted by $G$. The vertex set and the edge set of a graph $G$ is denoted by $V(G)$ and $E(G)$, respectively. The degree of a vertex $v$ is denoted by $d(v)$, the multiplicity of the edge $(u, v)$ by $d(u, v)$. The Laplacian matrix of a graph $G$ means the following matrix $L$:

$$L(i, j) = \begin{cases} \quad -d(v_i) & \text{if } i = j \\ d(v_i, v_j) & \text{if } i \neq j. \end{cases}$$

Digraph means a (weakly) connected directed graph that can have multiple edges but no loops. We usually denote a digraph by $D$. The vertex set and edge set are again denoted by $V(D)$ and $E(D)$, respectively. For a vertex $v$ the
indegree and the outdegree of \(v\) are denoted by \(d^-(v)\) and \(d^+(v)\), respectively. A digraph \(D\) is Eulerian if \(d^+(v) = d^-(v)\) for each vertex \(v \in V(D)\). The head of the directed edge \((u, v) \in E(D)\) is \(v\), and the tail of the edge is \(u\). The multiplicity of the directed edge \((u, v)\) is denoted by \(\overrightarrow{d}(u, v)\).

The maximum of all the indegrees and the outdegrees of \(D\) is denoted by \(\Delta(D)\), i.e., \(\Delta(D) = \max_{v \in V(D)} \max\{d^-(v), d^+(v)\}\). The Laplacian matrix of a digraph \(D\) means the following matrix \(L:\)

\[
L(i, j) = \begin{cases} 
-\overrightarrow{d}(v_i) & \text{if } i = j \\
\overrightarrow{d}(v_j, v_i) & \text{if } i \neq j.
\end{cases}
\]

A feedback arc set of a digraph \(D\) is a set of edges \(F \subseteq E(D)\) such that the digraph \(D' = (V(D), E(D) \setminus F)\) is acyclic. We denote \(\minfas(D) = \min\{|F| : F \subseteq E(D) \text{ is a feedback arc set}\}\).

Let \(G\) be a graph. An orientation of \(G\) is a directed graph \(D\) obtained from \(G\) by directing each edge. We identify the vertices of \(G\) with the corresponding vertices of \(D\). We denote the indegree and the outdegree of a vertex \(v \in V(G)\) in the orientation \(D\) by \(d^+_D(v)\) and \(d^-_D(v)\), respectively.

For a graph \(G\) let us denote by \(\mathbf{0}_G\) the vector with each coordinate equal to 0, where the coordinates are indexed by the vertices of the graph. For a vertex \(v\) of \(G\) we denote the characteristic vector of \(v\) by \(\mathbf{1}_v\). We use the same notations for digraphs.

2.2. Riemann-Roch theory on graphs

In this section we give some basic definitions of the Riemann-Roch theory on graphs.

The basic objects are called divisors. For a graph \(G\), Div\((G)\) is the free abelian group on the set of vertices of \(G\). An element \(f \in \text{Div}(G)\) is called divisor. We will either think of a divisor \(f \in \text{Div}(G)\) as a function \(f : V(G) \rightarrow \mathbb{Z}\), or as a vector \(f \in \mathbb{Z}^{|V(G)|}\) where the coordinates are indexed by the vertices of the graph.

The degree of a divisor is the following:

\[
\deg(f) = \sum_{v \in V(G)} f(v).
\]

The following equivalence relation on Div\((G)\) is called linear equivalence: For \(f, g \in \text{Div}(G)\), \(f \sim g\) if there exists a \(z \in \mathbb{Z}^{|V(G)|}\) such that \(g = f + Lz\).

A divisor \(f \in \text{Div}(G)\) is effective, if \(f(v) \geq 0\) for each \(v \in V(G)\).

**Definition 2.1** (The rank of a divisor). For a divisor \(f \in \text{Div}(G)\), the rank of \(f\) is

\[
\text{rank}(f) = \min\{\deg(g) - 1 : g \in \text{Div}(G), g \text{ is effective, } \exists h \in \text{Div}(G) \text{ such that } h \sim f - g \text{ and } h \text{ is effective}\}.
\]

If we wish to emphasize the underlying graph, we write \(\text{rank}_G(f)\) instead of \(\text{rank}(f)\).
2.3. Chip-firing

It was noted already by Baker and Norine [2], that there is a duality between divisors on graphs and the objects of the chip-firing game, as defined by Björner, Lovász and Shor [4]. Using this duality we can translate some questions in divisor theory to questions in chip-firing. We would like to use the latter language in the article, so let us include here a short introduction to chip-firing.

Remark 2.2. Often the term “chip-firing game” is used also in the setting of Baker and Norine, but for clarity, we only use this term for the game of [4].

The theory of chip-firing games was developed both for graphs (see e.g. [4]) and digraphs (see e.g. [3]). Though the notions of the Riemann-Roch theory on graphs are in duality with notions concerning the chip-firing game on undirected graphs, later on, we will also need chip-firing on digraphs.

The basic idea is that on each vertex of a graph (or digraph), there is a certain amount of chips. If a vertex has at least as many chips as its degree (in the directed case: as its outdegree), then it can be fired. In the undirected case, this means, that the vertex passes a chip to its neighbors along each edge incident to it (and so the number of chips on itself decreases by its degree). In the directed case, the fired vertex passes a chip along each outgoing edge. (In fact if we think of an undirected graph as a special digraph where we replace each edge by a pair of oppositely directed edges, then the two definitions coincide for these graphs.)

Now we give the exact definitions.

Let $H$ be an undirected graph or a digraph. A chip-distribution, or distribution, is a function $x : V(H) \to \mathbb{Z}^+ \cup \{0\}$. We sometimes say: vertex $v$ has $x(v)$ chips. We use the notation $|x|$ for the number of chips in the distribution $x$, i.e., $|x| = \sum_{v \in V(H)} x(v)$. We denote the set of chip-distributions on $H$ by $\text{Chip}(H)$.

Firing a vertex $v$, as mentioned before, means taking the new chip-distribution $x + L1_v$ instead of $x$. (Note that the Laplacian matrix $L$ is different in the undirected and in the directed case, and that in both cases $|x + L1_v| = |x|$ so a firing preserves the number of chips.) A vertex $v \in V(H)$ is active (with respect to $x$) if after firing it, it still has a nonnegative number of chips, i.e., in the undirected case if $x(v) \geq d(v)$, while in the directed case if $x(v) \geq d^+(v)$. The firing of a vertex $v \in V(H)$ is legal, if $v$ was active before the firing. A legal game is a sequence of distributions in which every distribution is obtained from the previous one by a legal firing. A game terminates if there is no active vertex with respect to the last distribution.

The following theorem was proved by Björner, Lovász and Shor for undirected graphs and by Björner and Lovász for digraphs. (Originally the theorem for the undirected case was proved for simple graphs, but the proof works also for graphs with multiple edges.)

**Theorem 2.3** ([4, Theorem 1.1], [3, Theorem 1.1]). Let $H$ be a graph or a digraph and let $x \in \text{Chip}(H)$ be a distribution. Then starting from $x$, either every legal game can be continued indefinitely, or every legal game terminates.
after the same number of moves with the same final distribution. Moreover, the number of times a given node is fired is the same in every legal game.

Let us call a chip-distribution \( x \in \text{Chip}(H) \) finite, if every legal chip-firing game played starting from \( x \) is finite, and call it infinite, if every legal chip-firing game played starting from \( x \) can be continued indefinitely. According to Theorem 2.3, a chip-distribution is either finite or infinite.

It can easily be seen by the pigeonhole principle that if for a graph \( G \) a distribution \( x \in \text{Chip}(G) \) has \( |x| > 2|E(G)| - |V(G)| \) then \( x \) is infinite (see [4]). And similarly for a digraph \( D \) if a distribution \( x \in \text{Chip}(D) \) has \( |x| > |E(D)| - |V(D)| \) then \( x \) is infinite (see [3]).

From this it follows that the following quantity, which measures how far a given distribution is from being infinite, is well defined. For a distribution \( x \in \text{Chip}(H) \), let

\[
\text{dist}(x) = \min \{|y| : y \in \text{Chip}(H), x + y \text{ is infinite} \}.
\]

We say that \( \text{dist}(x) \) is the distance of \( x \) from infinite distributions.

Note that \( \text{dist}(0_H) \) is exactly the minimum number of chips in an infinite distribution on the graph/digraph \( H \).

2.4. Chip-firing and the Riemann-Roch theory

Now we describe the duality between divisors on graphs and chip-distributions discovered by Baker and Norine [2].

Let \( G \) be a graph and let \( K^+ = K^+_G \) be the chip-distribution with \( K^+(v) = d(v) - 1 \) for each \( v \in V(G) \). For a divisor \( f \in \text{Div}(G) \) with \( f(v) \leq d(v) - 1 \) for each \( v \in V(G) \), we have \( (K^+ - f)(v) \geq 0 \) for each \( v \in V(G) \), therefore \( K^+ - f \in \text{Chip}(G) \). We call \( K^+ - f \) the dual pair of \( f \).

**Proposition 2.4** ([2, Corollary 5.4]). For a divisor \( f \in \text{Div}(G) \) with \( f(v) \leq d(v) - 1 \) for each \( v \in V(G) \), there exists an effective divisor equivalent to \( f \) if and only if \( K^+ - f \) is a finite distribution.

**Remark 2.5.** We could have defined the chip-firing game for not necessarily nonnegative distributions as well with the same rules (only active vertices can fire). In this case Theorem 2.3 would still hold, and we could have a dual pair for any divisor, but this is not necessary for our purposes.

The following is a straightforward consequence of Proposition 2.4.

**Proposition 2.6.** Let \( f \in \text{Div}(G) \) be a divisor with \( f(v) \leq d(v) - 1 \) for each \( v \in V(G) \), and let \( x \in \text{Chip}(G) \) be its dual pair. Then \( \text{rank}(f) = \text{dist}(x) - 1 \).

2.5. NP-hardness results

In Section 3, based on recent results of Perrot and Pham [5], we prove the following.
Theorem 2.7. Given a digraph $D$, computing $\text{dist}(0_D)$ is $\text{NP}$-hard, even for Eulerian digraphs.

Using this result we prove the main theorem of this article.

Theorem 2.8. For a distribution $x \in \text{Chip}(G)$ on a graph $G$, computing $\text{dist}(x)$ is $\text{NP}$-hard.

The proof can be found in Section 4. As a corollary of the theorem and Proposition 2.6, we get the following.

Corollary 2.9. For a divisor $f \in \text{Div}(G)$ on a graph $G$, computing $\text{rank}(f)$ is $\text{NP}$-hard, even for a divisor $f$ with $f(v) \leq d(v) - 1$ for every $v \in V(G)$.

In [5], Hladký, Král’ and Norine proved the following statement:

Proposition 2.10 ([5, Corollary 22.]). Let $f$ be a divisor on a graph $G$. Let $G'$ be the simple graph obtained from $G$ by subdividing each edge of $G$ by an inner point and let $f'$ be the divisor on $G'$ that agrees with $f$ on the vertices of $G$ and has value 0 on new points. Then $\text{rank}_G(f) = \text{rank}_{G'}(f')$.

By dualizing this statement, we get the following: For a distribution $x \in \text{Chip}(G)$, if we get $x' \in \text{Chip}(G')$ from $x$ so that we put $d(v) - 1 - 0 = 1$ chip on each new vertex, and on the vertices of $G$, $x'$ agrees with $x$, then $\text{dist}_G(x) = \text{rank}_G(K_G^+ - x) + 1 = \text{rank}_{G'}(K_{G'}^+ - x') + 1 = \text{dist}_{G'}(x')$.

From this observation and Proposition 2.10 we get the following corollaries:

Corollary 2.11. For a distribution $x \in \text{Chip}(G)$ on a simple graph $G$, computing $\text{dist}(x)$ is $\text{NP}$-hard.

Corollary 2.12. For a divisor $f \in \text{Div}(G)$ on a simple graph $G$, computing $\text{rank}(f)$ is $\text{NP}$-hard.

Using another result of [5], we get that computing the rank of divisors is also $\text{NP}$-hard for so called tropical curves. Informally, a metric graph is a graph, where each edge has a positive length, and we consider our graph to be a metric space (the inner points of the edges are also points of this metric space). Tropical curve is more general in that we also allow some edges incident with vertices of degree one to have infinite length. A divisor on a tropical curve is an integer-valued function on the curve with only finitely many nonzero values. The notions of the degree of a divisor, linear equivalence, effective divisor and the rank can be defined as well, see [5].

The metric graph $\Gamma$ corresponds to the graph $G$, if $\Gamma$ is obtained from $G$ by setting the length of each edge to be 1.

Theorem 2.13 ([5, Theorem 3]). Let $f$ be a divisor on a graph $G$, and $\Gamma$ be the metric graph corresponding to $G$. Then $\text{rank}_G(f) = \text{rank}_\Gamma(f)$.

As a metric graph is a special tropical curve, we get the following:

Corollary 2.14. For a tropical curve $\Gamma$, $f \in \text{Div}(\Gamma)$, computing $\text{rank}(f)$ is $\text{NP}$-hard.
3. Minimal infinite distributions on Eulerian digraphs

In this section we prove Theorem 2.7 that says that computing the minimum number of chips in an infinite distribution is \textbf{NP}-hard for an Eulerian digraph \(D\).

We will use the method of Perrot and Pham. In the paper \cite{PerrotPham}, they proved the \textbf{NP}-hardness of an analogous question in the abelian sandpile model (which is a closely related variant of the chip-firing game).

Using the ideas of \cite{PerrotPham}, we first give a formula for the minimum number of chips in an infinite distribution on an Eulerian digraph.

As a motivation, let us have a look at the analogous question on undirected graphs, which was solved by Björner, Lovász and Shor.

\textbf{Theorem 3.1 (\cite{BjornerLovaszShor}, Theorem 2.3).} Let \(G\) be a graph. Then \(\text{dist}(0_G) = |E(G)|\).

We sketch the proof as a motivation for the directed case.

\textbf{Proof.} First we prove the following useful lemma.

\textbf{Lemma 3.2 (\cite{BjornerLovaszShor}).} Let \(D\) be an acyclic orientation of \(G\) and let \(x \in \text{Chip}(G)\) be a distribution with \(x(v) \geq d(v) - D(v)\) for each \(v \in V(G)\). Then \(x\) is infinite.

\textbf{Proof.} Since the orientation is acyclic, there is a sink, i.e., a vertex \(v_0 \in V(G)\) with \(d(v_0) = d^{-}_D(v_0) \leq x(v_0)\). Hence \(v_0\) is active with respect to \(x\). Fire \(v_0\) and denote the resulting distribution by \(x'\). Reverse the direction of the edges incident to \(v_0\) and denote the resulting directed graph by \(D'\). It is easy to see that \(D'\) is acyclic and \(d^{-}_{D'}(v) \leq x'(v)\) for each \(v \in V(G)\). Hence we can repeat the above argument. This shows that the distribution \(x\) is indeed infinite. \(\square\)

Now taking an acyclic orientation \(D\) of \(G\) and setting \(x(v) = d^{-}_D(v)\) for each \(v \in V(G)\) we have a distribution with \(|x| = |E(G)|\) that is infinite from the lemma. This shows that \(\text{dist}(0_G) \leq |E(G)|\).

For proving \(\text{dist}(0_G) \geq |E(G)|\), take an infinite distribution \(x \in \text{Chip}(G)\). It is enough to show that \(|x| \geq |E(G)|\). Since in an infinite game every vertex is fired infinitely often (see \cite{BjornerLovaszShor}, Lemma 2.1), after finitely many firings, every vertex of \(G\) has been fired at least once. Let \(x'\) be the distribution at such a moment. Then \(|x| = |x'|\). Let \(D\) be the orientation of \(G\) that we get by directing each edge toward the vertex whose last firing occurred earlier. It is straightforward to check that \(x'(v) \geq d^{-}_{D'}(v)\) for each \(v \in V(G)\). This fact implies that \(|x| = |x'| \geq |E(G)|\), completing the proof. \(\square\)

In contrast, in the directed case only the following lower bound is known for the minimum number of chips in an infinite game.

\textbf{Theorem 3.3 (\cite{BjornerLovaszShor}, Theorem 2.2).} Let \(D\) be a strongly connected digraph and let \(h\) denote the maximum number of edge-disjoint directed cycles in \(D\). Then any game with fewer than \(h\) chips is finite.

We show the following in the case if \(D\) is Eulerian (note that this implies that \(D\) is strongly connected).
Theorem 3.4. Let \( D \) be an Eulerian digraph. Then \( \text{dist}(0) = \minfas(D) \).

The proof follows \cite{[7]}. Its idea can be thought of as the generalization of the idea of the proof of Theorem 3.1.

For proving Theorem 3.4 we need a classical result about chip-firing on an Eulerian digraph:

Proposition 3.5 (\cite{[3], Lemma 2.1}). On an Eulerian digraph \( D \) if a chip-distribution is infinite then in any legal game every vertex is fired infinitely often.

Now we prove Theorem 3.4.

Proof of Theorem 3.4. The key lemma is the following observation of Perrot and Pham (they proved it for the recurrent configurations of the abelian sandpile model, but the two models are very closely related).

Lemma 3.6 (\cite{[7]}). Let \( F \subseteq E(D) \) be a minimum cardinality feedback arc set. Denote by \( d_F^-(v) \) and \( d_F^+(v) \) the outdegree and indegree of a vertex \( v \) in the digraph \( D_F = (V(D), F) \). Then a distribution \( x \in \text{Chip}(D) \) satisfying

\[
x(v) \geq d_F^-(v) \quad \text{for every} \quad v \in V(D)
\]

is infinite.

Proof. First we prove that if \( F \) is a minimum cardinality feedback arc set then there exists a vertex \( v \in V(D) \) such that among the edges incident to \( v \), \( F \) contains exactly the in-edges of \( v \).

Let \( A = E(D) \setminus F \). From the definition of feedback arc set, \( D_A = (V(D), A) \) is an acyclic graph. Therefore it has a source \( v_0 \). We claim that no out-edge of \( v_0 \) is in \( F \). Indeed, if some out-edges of \( v_0 \) would be in \( F \), removing them from \( F \) would mean adding some out-edges to the source \( v_0 \) in \( D_A \), which cannot create a cycle. So we could get a smaller feedback arc set.

The fact that \( v_0 \) is a source in \( D_A \) means that all the in-edges of \( v_0 \) are in \( F \). Hence from the edges incident to \( v_0 \), \( F \) contains exactly the in-edges of \( v_0 \).

Now take such a vertex \( v_0 \). From \cite{[5]}, the choice of \( v_0 \) and the fact that \( D \) is Eulerian, we have that \( x(v_0) \geq d_F^-(v_0) = d^-(v_0) = d^+(v_0) \), therefore \( v_0 \) is active with respect to \( x \). Fire \( v_0 \). Let \( x' \) be the resulting distribution. We show, that we can modify the feedback arc set \( F \), such that for the new feedback arc set \( F' \) we have \( x'(v) \geq d_{F'}^-(v) \) for every \( v \in V(D) \).

Let \( F' \) be the set of arcs obtained from \( F \) by removing the in-edges of \( v_0 \) and adding the out-edges of \( v_0 \) (see Figure 1). Then \( D_{A'} = (V(D), A') \) with \( A' = E(D) \setminus F' \) is acyclic, since the new edges are all incident to a sink in \( D_{A'} \). Moreover, since \( D \) is Eulerian, and from the choice of \( v_0 \), we have \( |F'| = |F| \), hence \( F' \) is also a feedback arc set of minimum cardinality. It is straightforward to check that indeed \( x'(v) \geq d_{F'}^-(v) \) for every \( v \in V(D) \).

So we are again in the starting situation, which shows that \( x \) is indeed infinite. \( \square \)
Figure 1: An example for simultaneously firing a vertex and changing the feedback arc set. The arcs of the feedback arc sets are drawn by dashed lines.

Now take a feedback arc set $F$ of minimum cardinality, and let $x(v) = d_F(v)$ for every $v \in V(D)$. Then $|x| = |F| = \minfas(D)$, and from the lemma, $x$ is infinite. This proves that $\dist(0_D) \leq \minfas(D)$.

For proving $\dist(0_D) \geq \minfas(D)$, take an infinite distribution $x$. It is enough to prove that $|x| \geq \minfas(D)$.

Let us play a chip-firing game with initial distribution $x$. Proposition 3.5 says that after finitely many steps, every vertex has fired. Play until such a moment, and let the distribution at that moment be $x'$.

Let $A$ be the following set of edges:

$$ A = \{(u, v) \in E(D) : \text{the last firing of } u \text{ precedes the last firing of } v\}. $$

As every vertex has fired, $A$ is well defined. Let $v_1, v_2, \ldots, v_{|V(D)|}$ be the ordering of the vertices by the time of their last firing. Then $v_1, v_2, \ldots, v_{|V(D)|}$ is a topological order of $D_A = (V(D), A)$, so $D_A$ is acyclic, hence $F = E(D) \setminus A$ is a feedback arc set. We show that $x'(v) \geq d_F^{-}(v)$ for every $v \in V(D)$. For $1 \leq i \leq |V(D)|$ the vertex $v_i$ has $d_F^{-}(v_i) = \sum_{j \geq i} d(v_j, v_i)$. After its last firing, $v_i$ had a nonnegative number of chips. Since then, it kept all chips it received. And as $v_{i+1}, \ldots, v_{|V(D)|}$ all fired since the last firing of $v_i$, it received at least $\sum_{j > i} d(v_j, v_i) = d_F^{-}(v_i)$ chips. So indeed, we have $x'(v_i) \geq d_F^{-}(v_i)$.

Therefore $|x| = |x'| \geq |F| \geq \minfas(D)$.

Note that in the above setting, starting from $x'$, then firing the vertices in the order $v_1, v_2, \ldots, v_{|V(D)|}$ (once each) is a legal game. Indeed, we proved that $x'(v_i) \geq d_F^{-}(v_i) = \sum_{j > i} d(v_j, v_i)$. After firing $v_1, \ldots, v_{i-1}$, the vertex $v_i$ receives $\sum_{j < i} d(v_j, v_i)$ more chips, so it indeed becomes active ($d^+(v_i) = d^-(v_i) = \sum_{j \neq i} d(v_j, v_i)$ as we did not allow loops).
We will need this observation in the next section, so we state it as a proposition:

**Proposition 3.7.** In a chip-firing game on an Eulerian digraph $D$, if at some moment every vertex has already fired then there is an order of the vertices in which they can be legally fired once each, starting from that moment. \(\blacksquare\)

It is worth noting that on an Eulerian digraph if starting from an initial distribution $x$ we fired each vertex exactly once, then we get back to distribution $x$: each vertex $v$ gave and received $d^-(v) = d^+(v)$ chips.

Finally, we prove Theorem 2.7.

**Proof of Theorem 2.7.** Perrot and Pham proved that computing $\text{minfas}(D)$ for an Eulerian digraph $D$ is $\text{NP}$-hard [7, Theorem 2]. From this, and from Theorem 3.4, the statement follows. \(\blacksquare\)

### 4. The distance from infinite distributions is NP-hard on graphs

In this section we prove Theorem 2.8, the main theorem of this article.

In our proof of the $\text{NP}$-hardness, we rely on the fact that a finite chip-firing game on an Eulerian digraph $D$ terminates after at most $2|V(D)|^2|E(D)|\Delta(D)$ steps (see [3, Corollary 4.9]). With this in mind, we define the following transformation:

**Definition 4.1.** Let $\varphi$ be the following transformation, assigning an undirected graph $G = \varphi(D)$ to any digraph $D$:

- Split each directed edge by an inner point, and substitute the tail segment by $M = 8|V(D)|^2|E(D)|\Delta(D)$ parallel edges. Then forget the orientations.

- We maintain the effect of the transformation by a bijective function $\psi : (V(D) \cup E(D)) \to V(\varphi(D))$:

  - For a vertex $v \in V(D)$ let $\psi(v)$ be the corresponding vertex of $\varphi(D)$. For an edge $e \in E(D)$, let $\psi(e)$ be the vertex with which we have split $e$.

Then the degrees in $\varphi(D)$ are the following:

\[
d(v) = \begin{cases} 
    d^+\left(\psi^{-1}(v)\right) \cdot M + d^-\left(\psi^{-1}(v)\right) & \text{if } \psi^{-1}(v) \in V(D) \\
    M + 1 & \text{if } \psi^{-1}(v) \in E(D).
\end{cases}
\]

Let us define a certain chip-distribution on the graph $\varphi(D)$:

**Definition 4.2** (base-distribution). Let $\text{base}_D \in \text{Chip}(\varphi(D))$ on a vertex $v \in V(\varphi(D))$ be the following:

\[
\text{base}_D(v) = \begin{cases} 
    d^+\left(\psi^{-1}(v)\right) \cdot M & \text{if } \psi^{-1}(v) \in V(D) \\
    M/2 & \text{if } \psi^{-1}(v) \in E(D).
\end{cases}
\]

The key lemma in our proof of Theorem 2.8 is the following:

**Lemma 4.3.** For an Eulerian digraph $D$, $\text{dist}_D(0_D) = \text{dist}_{\varphi(D)}(\text{base}_D)$. 

10
Figure 2: A schematic picture for a digraph $D$ and the corresponding $\varphi(D)$. In the reality the multiple edges should be 1536-fold.

Proof. Let $G = \varphi(D)$. First we show that $\text{dist}_D(0_D) \geq \text{dist}_G(\text{base}_D)$.

Let $x \in \text{Chip}(D)$ be an infinite chip-distribution such that $|x|$ is minimal. We can assume that there is an order of the vertices of $D$ such that from initial distribution $x$ we can fire the vertices in that order (once each). Otherwise, from Proposition 3.5 we can play a chip-firing game from $x$ until each vertex has fired. Denoting the distribution at that moment by $x'$, from Proposition 3.7 for $x'$ there is such an order. As firing does not change the number of chips in the game, $|x'|$ is still minimal, so we can substitute $x$ with $x'$.

Let $y \in \text{Chip}(G)$ be the distribution “$x + \text{base}_D$”, i.e., for a vertex $v \in V(D)$ let $y(\psi(v)) = x(v) + \text{base}_D(\psi(v))$ and for an edge $e \in E(D)$ let $y(\psi(e)) = \text{base}_D(\psi(e))$. Since $y(w) \geq \text{base}_D(w)$ for each $w \in V(G)$ and $|y - \text{base}_D| = |x| = \text{dist}_D(0_D)$, it is enough to show that $y$ is infinite.

For that, it is enough to show that we can fire each vertex of $G$ exactly once in some order. Then each vertex $w \in V(G)$ gives and receives $d(w)$ chips, so we get back to the distribution $y$ and can repeat this period indefinitely.

To get such an order of the vertices of $G$, we will play the chip-firing game simultaneously on $D$ and $G$.

To firing a vertex $v$ in $D$, let the corresponding firings in $G$ be: Fire $\psi(v)$, then fire $\psi(e)$ for every out-edge $e$ of $v$ (in some order).

Claim 4.4. If a sequence of firings of length $k \leq M/2$ on $D$ with initial distribution $x$ is legal then the sequence of the corresponding firings on $G$ with initial distribution $y$ is also legal. Moreover, if we denote the resulting distribution on $D$ by $\tilde{x}$ and on $G$ by $\tilde{y}$ then

$$\tilde{y}(\psi(v)) = \tilde{x}(v) + d^+(v) \cdot M \text{ for each } v \in V(D)$$  \hspace{1cm} (4.1)
each vertex exactly once. This finishes the proof of the direction \( \text{dist} \) of the corresponding firings on a minimal infinite chip-distribution with \( \text{base} \) and \( y \). Note first that for an edge \( e \) and \( y \), we can fire the vertices of \( \text{dist} \) with the sufficient number of chips to fire. Consequently, using (4.1) of the induction hypothesis, we have that \( M + y'(\text{dist}(e)) \geq M + M/2 - (k - 1) \geq M + 1 = d(\text{dist}(e)) \) chips. Fire these vertices in an arbitrary order. (Firing one leaves the others active.) Denote by \( y'' \) the resulting distribution. It is easy to check that the distributions \( x'' \) and \( y'' \) satisfy conditions (4.1) and (4.2).

We have chosen the distribution \( x \) such that we can fire the vertices of \( D \) in some order (once each) with initial distribution \( x \). This is a legal sequence of firings of length \( |V(D)| < M/2 \). According to the previous claim, the sequence of the corresponding firings on \( G \) is also legal. Moreover, on \( G \) we also fire each vertex exactly once. This finishes the proof of the direction \( \text{dist}_D(\text{base}_D) \) ≥ \( \text{dist}_G(\text{base}_D) \).

Now we prove that \( \text{dist}_D(0_D) \) ≤ \( \text{dist}_G(\text{base}_D) \). For this, let \( y \in \text{Chip}(G) \) be a minimal infinite chip-distribution with \( \text{base}_D(w) \leq y(w) \) for each \( w \in V(G) \). Let \( x(v) = y(\text{dist}(v)) - \text{base}_D(\text{dist}(v)) \) on each \( v \in V(D) \). It is enough to show that \( x \) is infinite.

First note that \( \text{dist}_D(0_D) \) ≤ \( |E(D)| - |V(D)| + 1 \), since having a chip-distribution with at least \( |E(D)| - |V(D)| + 1 \) chips, at every stage of the game at least one of the vertices has the sufficient number of chips to fire. Consequently, using also the first part of the lemma, we have that \( |y - \text{base}_D| = \text{dist}_G(\text{base}_D) \) ≤ \( \text{dist}_D(0_D) \) ≤ \( |E(D)| - |V(D)| + 1 \) ≤ \( \frac{1}{2}M \).

Now we play the game on \( G \) and \( D \) simultaneously from initial distributions \( y \) and \( x \), respectively, in the following way. Let a step be the following: Choose a vertex \( v \in V(D) \) for which \( \text{dist}(v) \) can fire. On \( G \) fire \( \text{dist}(v) \), then for every out-edge \( e \) of \( v \), fire \( \text{dist}(e) \). On \( D \) fire \( v \).

We show that for \( \frac{3}{8}M \geq 2|V(D)|^2|E(D)|\Delta(D) + 1 \) steps we can play this legally on both graphs. Note first that for an edge \( e \) of \( D \), the change of the number of chips on \( \text{dist}(e) \) is at most one after each step. Hence at the beginning of a step a vertex of \( G \) of the form \( \text{dist}(e) \) can have at most \( \frac{M}{2} + |y - \text{base}_D| + \frac{3}{4}M \leq M/2 + \frac{1}{8}M + \frac{3}{4}M < M + 1 = d(\text{dist}(e)) \) chips, so it cannot be fired. It also follows from this that on every such vertex the number of chips is positive, since it is at least \( \frac{M}{2} - \frac{1}{8}M > 0 \). But \( y \) is an infinite distribution, hence at the beginning of a step we can find an active vertex, which therefore must be of the form \( \text{dist}(v) \) with \( v \in V(D) \). After firing \( \text{dist}(v) \), \( \text{dist}(e) \) becomes active for every out-edge \( e \) of
using Lemma 3.2, \( v \), since \( \psi(e) \) had a positive number of chips at the beginning of the step, and received \( M \) chips. Hence on \( G \) we can play in the desired way for \( \frac{5}{8} M \) steps.

For the initial distributions, we have \( y(\psi(v)) = d^+(v) \cdot M + x(v) \) for each \( v \in V(D) \), so a vertex \( v \in V(D) \) is active with respect to \( x \) if and only if \( \psi(v) \) is active with respect to \( y \). Let \( x' \) be the distribution on \( D \) and \( y' \) the distribution on \( G \) at the end of an arbitrary (but at most \( \frac{5}{8} M \text{th} \) step. Then it can be shown by induction that \( y'(\psi(v)) = d^+(v) \cdot M + x'(v) \) for each \( v \in V(D) \). So in each step we have that a vertex \( v \in V(D) \) is active if and only if \( \psi(v) \) is active.

Hence for \( \frac{5}{8} M \) steps, the corresponding game on \( D \) is also legal. This means that there is a chip-firing game of length at least \( \frac{5}{8} M \geq 2|V(D)|^2|E(D)|\Delta(D)+1 \) on \( D \) with initial distribution \( x \), which by Corollary 4.9 implies that the distribution \( x \) is infinite. This finishes the proof.

**Proof of Theorem 2.8.** The theorem is an easy consequence of Theorem 2.7 and Proposition 5.1. Therefore dist(\( x \)) ≥ |V(G)| − |x|.

**5. Polynomial time computability in a special case**

In this section we consider undirected graphs, and observe that for chip-distributions that are in a sense “small”, computing the distance from infinite distributions can be done in polynomial time. Moreover, for these distributions, the distance from infinite distributions only depends on the number of edges of the graph and the number of chips in the distribution.

Recall that Theorem 3.1 stated that dist(\( 0_G \)) = |E(G)| for any undirected graph \( G \). We would like to generalize this statement for “small enough” distributions.

We say that a distribution \( x \in \text{Chip}(G) \) is under an acyclic orientation, if there exists an acyclic orientation \( D \) of \( G \) such that \( x(v) = d_D^-(v) \) for each \( v \in V(G) \).

**Proposition 5.1.** Let \( G \) be a graph and let \( x \in \text{Chip}(G) \) be a distribution. If \( x \) is under an acyclic orientation then dist(\( x \)) = |E(G)| − |x|.

**Proof.** From Theorem 3.1, an infinite distribution has at least \( |E(G)| \) chips, therefore dist(\( x \)) ≥ |E(G)| − |x|.

For the other direction, let \( D \) be an acyclic orientation of \( G \) with \( x(v) ≤ d_D^-(v) \) for each \( v \in V(G) \). Let \( y \) be the distribution on \( G \) corresponding to the indegrees of the orientation, i.e., \( y(v) = d_D^-(v) \) for each \( v \in V(G) \). Then, using Lemma 5.2, \( y \) is infinite, moreover \( |y| = |E(G)| \) and \( y(v) ≥ x(v) \) for each \( v \in V(G) \). Hence dist(\( x \)) ≤ |y − x| = |E(G)| − |x|. This completes the proof of the proposition.

It can also be decided quickly whether a distribution \( x \in \text{Chip}(G) \) is under an acyclic orientation.

**Proposition 5.2.** Let \( G \) be a graph and let \( x \in \text{Chip}(G) \) be a distribution. There is a polynomial time algorithm that decides whether \( x \) is under an acyclic orientation.
Proof. The algorithm repeats the following step: If there is a vertex \( v \) such that \( x(v) = 0 \) then remove \( v \) and each edge incident to \( v \) from the graph, and for each neighbor \( u \) of \( v \), replace \( x(u) \) with \( \max\{x(u) - d(u,v), 0\} \). If the algorithm reaches the empty graph, then it returns that \( x \) is under an acyclic orientation. If at an arbitrary step there is no vertex \( v \) with \( x(v) = 0 \) then it returns that \( x \) is not under an acyclic orientation.

Now we prove the correctness of the algorithm. First consider the case when the algorithm finishes after reaching the empty graph. Take the orientation \( D \) of \( G \) in which each edge is oriented towards the vertex removed later. This orientation is acyclic, because the order of removals is a topological order. We show that \( x(v) \leq d_D^-(v) \) for each vertex \( v \in V(G) \). Let \( v \in V(G) \) be an arbitrary vertex. Then

\[
d_D^-(v) = \sum_{u \text{ is removed before } v} d(u,v).
\]

When removing a vertex \( u \), the number of chips on \( v \) decreases by at most \( d(u,v) \). When \( v \) is removed from the graph it has 0 chips, hence \( x(v) \leq d_D^-(v) \), showing that \( x \) is under an acyclic orientation.

Now suppose that the algorithm stops before reaching the empty graph. Let \( X \cup Y \) be the partition of \( V(G) \), where \( Y \) is the set of vertices removed by the algorithm and \( X \neq \emptyset \) is the set of vertices that remained. Suppose that there is indeed an acyclic orientation \( D \) of \( G \) satisfying \( x(v) \leq d_D^-(v) \) for each \( v \in V(G) \). The subgraph of \( D \) induced by \( X \), \( D[X] \), is also acyclic, hence it has a source, i.e., a vertex \( v_0 \in X \) such that there is no directed edge in \( D \) from \( X \setminus \{v_0\} \) to \( v_0 \). We show that after the algorithm removes each vertex in \( Y \), it can also remove \( v_0 \).

After removing the vertices in \( Y \), \( v_0 \) has \( \max\{x(v_0) - \sum_{u \in Y} d(u,v_0), 0\} \) chips. From our assumptions that \( x \) is under \( D \) and \( v_0 \) is a source in \( D[X] \), \( x(v_0) \leq d_D^-(v_0) \leq \sum_{u \in Y} d(u,v_0). \) Therefore after removing the vertices in \( Y \), \( v_0 \) indeed has 0 chips, so it can be removed, which contradicts our assumption. \( \square \)

Now using Proposition 2.4, we state the corollaries of the previous propositions for the case of divisors.

Let \( G \) be a graph. We say that a divisor \( f \in \text{Div}(G) \) is \textit{almost over an acyclic orientation} if there is an acyclic orientation \( D \) of \( G \) such that \( f(v) \geq d_D^+(v) - 1 \) for each \( v \in V(G) \).

**Corollary 5.3.** Let \( G \) be a graph and let \( f \in \text{Div}(G) \) be a divisor. If \( f \) is almost over an acyclic orientation then \( \text{rank}(f) = |V(G)| - |E(G)| + \deg(f) - 1. \)

**Corollary 5.4.** Let \( G \) be a graph and let \( f \in \text{Div}(G) \) be a divisor. There is a polynomial time algorithm that decides whether \( f \) is almost over an acyclic orientation.

Acknowledgement

We would like to thank Erika Bérczi-Kovács and Kristóf Bérczi for suggesting us to try to reduce the feedback arc set problem to the computation of the
rank, and thus setting us on this problem. We would also like to thank Tamás Király, Zoltán Király and Márton Elekes for their useful comments about the manuscript.
