Abstract

Communal pairing in superconductors introduces variational freedom for Cooper pairs to share fermions. Temporal oscillations of the superconducting gap entropically drive communal pairing through the order by disorder phenomenology, stabilising a finite momentum space width of the superconducting gap that increases with interaction strength, creating a smooth evolution from the weakly interacting BCS state to the strongly interacting BEC state.

1 Introduction

The microscopic description of superconductivity by Bardeen, Cooper, and Schrieffer (BCS) [1] is one of the historic milestones of condensed matter physics, accurately describing a host of materials [2, 3, 4, 5], and serving as the foundation for numerous theoretical extensions and numerical studies, such as Eliashberg theory [6], FFLO theory [7, 8], breached superconductivity [9, 10, 11], the T-matrix formulation of the BEC-BCS crossover [12], quantum Monte Carlo studies of the weakly interacting [13] and unitarity limits [14], studies on the effects of mass imbalances [15, 16], 3-body effects [17] and the more recent communal pairing theory [18, 19]. Central to the usual formulation of BCS theory is the assumption that the Cooper pairs condense only in the zero net momentum state, an assumption that is challenged by communal pairing theory [18, 19, 20].

Communal pairing as originally derived [18] showed that it is energetically favourable for Cooper pairs to share fermions. By considering the quantities $N_\sigma$ with $\sigma \in \{\uparrow, \downarrow\}$, where $N_\uparrow$ is the number of up-spin fermions any particular down-spin fermion is paired with, and vice versa, communal pairing theory predicts an optimal ratio of communal state indices of $N_\uparrow / N_\downarrow = 1$ for the spin-balanced BCS system and $N_\uparrow / N_\downarrow \neq 1$ in a spin-imbalanced system [19, 20]. The central paradigm shift that a finite gap may be present at non-optimal pairing momenta allows $N_\uparrow$ and $N_\downarrow$ to be greater than 1. It is therefore natural to ask whether as interactions get stronger in a spin-balanced BCS system, multiple Cooper pairs will share fermions, $N_\uparrow > 1$ and $N_\downarrow > 1$, to increase correlations. The variational principle ensures that the inclusion of additional freedom to form correlations will certainly not increase the ground state energy so can only lower it. This paper explores the extent of communality on spin-balanced systems. We do this by extending BCS theory, complementary to other additional effects, such as retardation as in Eliashberg theory [6] or induced Gor’kov-Melik-Barkhudarov interactions (GMB) [21, 22]. We will focus our discussion on 2D systems as communality is predicted to be enhanced in low dimensions [18, 19, 20] and because the results may be derived analytically here, but will also derive equivalent 3D results where possible. We will also be pre-emptively setting $N_\uparrow = N_\downarrow = N_q$ to reflect the fact that the system is spin-balanced.

In the next section we briefly recap conventional superconductivity from a field theoretic perspective and note the main difficulty with an exact treatment. Section 3 analyses single superconducting channels, making a distinction between static and oscillating channels before we combine these results into a minimally coupled model of multiple active superconducting channels in Section 4, making clear the connection to the BEC-BCS crossover. Conclusions are summarised in Section 5.

2 Quantum action

To start our analysis from a secure theoretical footing, we analyse the quantum partition function of a fermion gas with attractive contact interactions of strength $g$,

$$Z = \int \mathcal{D}\psi \mathcal{D}\bar{\psi} \exp(-S[\bar{\psi}, \psi])$$

where

$$S[\bar{\psi}, \psi] = \int d\tau dx \left[ \sum_\sigma \bar{\psi}_\sigma (\partial_\tau - \frac{\nabla^2}{2m} - \mu)\psi_\sigma - g\bar{\psi}_\uparrow \bar{\psi}_\downarrow \psi_\uparrow \psi_\downarrow \right]$$

is the quantum action, $\psi$ is a Grassman field with $\bar{\psi}$ its conjugate, $\tau$ the imaginary time goes from 0 to $\beta$ the inverse temperature, and $\sigma \in \{\uparrow, \downarrow\}$ denotes the spin-species. The fermions are of equal mass $m$ and we work in Hartree units so $\hbar = k_B = 1$. A Hubbard-Stratonovich decoupling in the Cooper channel yields the modified action

$$S[\bar{\psi}, \psi, \Delta^\ast, \Delta] = \int d\tau dx \left( \sum_\sigma \bar{\psi}_\sigma (\partial_\tau - \frac{\nabla^2}{2m} - \mu)\psi_\sigma - \Delta^\ast \bar{\psi}_\uparrow \psi_\downarrow - \Delta^\ast \psi_\uparrow \bar{\psi}_\downarrow + \frac{\Delta^\ast \Delta}{g} \right)$$
where the gap parameter is defined as \( \Delta = g\langle \psi_\uparrow \psi_\downarrow \rangle \) and is a function of both space and time \( \tau \). The Fourier transform of the gap is therefore generically a function of the pair momentum \( q \) and the frequency \( \Omega \), which label the various superconducting channels. In the weakly interacting limit, the gap is known to be isotropic and static and therefore the Fourier transform is a delta function in the momentum-frequency domain. However, in the strongly interacting limit, approaching the BEC-BCS crossover, communal pairing becomes confined to one channel. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion. Therefore, only one superconductor site spin fermion.

We first follow the standard BCS prescription to perform the Matsubara summation to obtain equation (1).

\[
S_{\Delta q}[\bar{\psi}, \psi, \Delta^*, \Delta] = \beta \sum_{k, \omega, \sigma} \bar{\psi}_{k, \omega, \sigma} (\omega + \xi_k) \psi_{k, \omega, \sigma} + \beta \sum_{q, \omega, \sigma} \left( \Delta_{q, \omega} \bar{\psi}_{q, \omega, \sigma} + \text{h.c.} \right)
\]

where \( \mathbf{k} \) and \( \mathbf{q} \) label momenta and pair momenta respectively, \( \omega \) is a fermionic Matsubara frequency, \( \Omega \) is a bosonic Matsubara frequency, \( \xi_k \equiv |k|^2/2m - \mu \) is the free particle dispersion less the chemical potential, \( \Delta_{\mathbf{q}, \omega} = g\sum_{\mathbf{k}, \omega} \psi_{\mathbf{k} + \mathbf{q}, \omega + \Omega} \bar{\psi}_{\mathbf{k}, \omega} \) are the Fourier components of the gap function and \( \text{h.c.} \) denotes the Hermitian conjugate.

We will ultimately consider communal pairing through multiple channels but to lay the foundation of the analysis, and connect to standard BCS theory, we will first decouple through a single \( \Delta_{\mathbf{q}, \omega} \) channel.

### 3 Decoupling in a single channel

We first follow the standard BCS prescription to perform the Matsubara summation to obtain equation (1).

\[
S_{\Delta q}[\bar{\psi}, \psi, \Delta^*, \Delta] = \beta \sum_{k, \omega, \sigma} \bar{\psi}_{k, \omega, \sigma} (\omega + \xi_k) \psi_{k, \omega, \sigma} + \beta \sum_{q, \omega, \sigma} \left( \Delta_{q, \omega} \bar{\psi}_{q, \omega, \sigma} + \text{h.c.} \right)
\]

where \( \mathbf{k} \) and \( \mathbf{q} \) label momenta and pair momenta respectively, \( \omega \) is a fermionic Matsubara frequency, \( \Omega \) is a bosonic Matsubara frequency, \( \xi_k \equiv |k|^2/2m - \mu \) is the free particle dispersion less the chemical potential, \( \Delta_{\mathbf{q}, \omega} = g\sum_{\mathbf{k}, \omega} \psi_{\mathbf{k} + \mathbf{q}, \omega + \Omega} \bar{\psi}_{\mathbf{k}, \omega} \) are the Fourier components of the gap function and \( \text{h.c.} \) denotes the Hermitian conjugate.

We will ultimately consider communal pairing through multiple channels but to lay the foundation of the analysis, and connect to standard BCS theory, we will first decouple through a single \( \Delta_{\mathbf{q}, \omega} \) channel.

\[
S_{\Delta q}[\bar{\psi}, \psi, \Delta^*, \Delta] = \beta \sum_{k, \omega, \sigma} \bar{\psi}_{k, \omega, \sigma} (\omega + \xi_k) \psi_{k, \omega, \sigma} + \beta \sum_{q, \omega, \sigma} \left( \Delta_{q, \omega} \bar{\psi}_{q, \omega, \sigma} + \text{h.c.} \right)
\]

where \( \mathbf{k} \) and \( \mathbf{q} \) label momenta and pair momenta respectively, \( \omega \) is a fermionic Matsubara frequency, \( \Omega \) is a bosonic Matsubara frequency, \( \xi_k \equiv |k|^2/2m - \mu \) is the free particle dispersion less the chemical potential, \( \Delta_{\mathbf{q}, \omega} = g\sum_{\mathbf{k}, \omega} \psi_{\mathbf{k} + \mathbf{q}, \omega + \Omega} \bar{\psi}_{\mathbf{k}, \omega} \) are the Fourier components of the gap function and \( \text{h.c.} \) denotes the Hermitian conjugate.

We will ultimately consider communal pairing through multiple channels but to lay the foundation of the analysis, and connect to standard BCS theory, we will first decouple through a single \( \Delta_{\mathbf{q}, \omega} \) channel.

\[
S_{\Delta q}[\bar{\psi}, \psi, \Delta^*, \Delta] = \beta \sum_{k, \omega, \sigma} \bar{\psi}_{k, \omega, \sigma} (\omega + \xi_k) \psi_{k, \omega, \sigma} + \beta \sum_{q, \omega, \sigma} \left( \Delta_{q, \omega} \bar{\psi}_{q, \omega, \sigma} + \text{h.c.} \right)
\]

where \( \mathbf{k} \) and \( \mathbf{q} \) label momenta and pair momenta respectively, \( \omega \) is a fermionic Matsubara frequency, \( \Omega \) is a bosonic Matsubara frequency, \( \xi_k \equiv |k|^2/2m - \mu \) is the free particle dispersion less the chemical potential, \( \Delta_{\mathbf{q}, \omega} = g\sum_{\mathbf{k}, \omega} \psi_{\mathbf{k} + \mathbf{q}, \omega + \Omega} \bar{\psi}_{\mathbf{k}, \omega} \) are the Fourier components of the gap function and \( \text{h.c.} \) denotes the Hermitian conjugate.

We will ultimately consider communal pairing through multiple channels but to lay the foundation of the analysis, and connect to standard BCS theory, we will first decouple through a single \( \Delta_{\mathbf{q}, \omega} \) channel.

\[
S_{\Delta q}[\bar{\psi}, \psi, \Delta^*, \Delta] = \beta \sum_{k, \omega, \sigma} \bar{\psi}_{k, \omega, \sigma} (\omega + \xi_k) \psi_{k, \omega, \sigma} + \beta \sum_{q, \omega, \sigma} \left( \Delta_{q, \omega} \bar{\psi}_{q, \omega, \sigma} + \text{h.c.} \right)
\]

where \( \mathbf{k} \) and \( \mathbf{q} \) label momenta and pair momenta respectively, \( \omega \) is a fermionic Matsubara frequency, \( \Omega \) is a bosonic Matsubara frequency, \( \xi_k \equiv |k|^2/2m - \mu \) is the free particle dispersion less the chemical potential, \( \Delta_{\mathbf{q}, \omega} = g\sum_{\mathbf{k}, \omega} \psi_{\mathbf{k} + \mathbf{q}, \omega + \Omega} \bar{\psi}_{\mathbf{k}, \omega} \) are the Fourier components of the gap function and \( \text{h.c.} \) denotes the Hermitian conjugate.

We will ultimately consider communal pairing through multiple channels but to lay the foundation of the analysis, and connect to standard BCS theory, we will first decouple through a single \( \Delta_{\mathbf{q}, \omega} \) channel.

\[
S_{\Delta q}[\bar{\psi}, \psi, \Delta^*, \Delta] = \beta \sum_{k, \omega, \sigma} \bar{\psi}_{k, \omega, \sigma} (\omega + \xi_k) \psi_{k, \omega, \sigma} + \beta \sum_{q, \omega, \sigma} \left( \Delta_{q, \omega} \bar{\psi}_{q, \omega, \sigma} + \text{h.c.} \right)
\]

where \( \mathbf{k} \) and \( \mathbf{q} \) label momenta and pair momenta respectively, \( \omega \) is a fermionic Matsubara frequency, \( \Omega \) is a bosonic Matsubara frequency, \( \xi_k \equiv |k|^2/2m - \mu \) is the free particle dispersion less the chemical potential, \( \Delta_{\mathbf{q}, \omega} = g\sum_{\mathbf{k}, \omega} \psi_{\mathbf{k} + \mathbf{q}, \omega + \Omega} \bar{\psi}_{\mathbf{k}, \omega} \) are the Fourier components of the gap function and \( \text{h.c.} \) denotes the Hermitian conjugate.

We will ultimately consider communal pairing through multiple channels but to lay the foundation of the analysis, and connect to standard BCS theory, we will first decouple through a single \( \Delta_{\mathbf{q}, \omega} \) channel.
The ultraviolet divergence of Eq. (2) is thus exactly cancelled, allowing us to take the sum over all k. Additionally, the first term on the right hand side of the regularization in Eq. (3) allows us to predict that the familiar exponential suppression factor $e^{-2/g_{y}F}$ seen in the solid-state BCS gap will be replaced with $1/k_F a$ in 2D and $e^{2/g_{y}F a}$ in 3D.

The action in 2D can be resolved analytically as

$$S_{q, \Omega} = -\frac{\beta m L^2}{4\pi} \left[ \mu_q \left( \sqrt{\Delta_{q, \Omega}^2 + \mu_q^2} - \mu_q \right) \right] - \frac{m a^2}{\sqrt{6}} \ln \left( \sqrt{\Delta_{q, \Omega}^2 + \mu_q^2} - \mu_q \right),$$

(4)

where $\mu_q \Omega \equiv \mu - \frac{a^2}{2m} + i \eta$ and we have neglected the finite temperature correction term. In 3D, the action may be evaluated in terms of an elliptic integral

$$S_{q, \Omega}^{(3D)} = -\frac{\beta m L^2}{\pi^2} \left[ \pi \left( \Delta_{q, \Omega}^{(3D)} \right)^2 \right]_{\Omega = 0} + \sqrt{2 m \mu_q^{(3D)}} I_1 \left( \frac{\Delta_{q, \Omega}^{(3D)}}{\mu_q^{(3D)}} \right),$$

where $I_1(z) \equiv \int_0^\infty dx x^2 \left( \sqrt{x^2 + (x^2 - 1)^2} - (x^2 - 1) - 2^2/2^2 \right)$ is a dimensionless function.

Now that we have derived an expression for the action we are well positioned to consider separately two cases, firstly the special case of $\Omega = 0$ before extending this to the finite $\Omega$ system.

### 3.1 Static single channel

The static action can be found by setting $\Omega = 0$ in Eq. (4) to obtain

$$S_q = -\frac{\beta m L^2}{4\pi} \left[ \mu_q \left( \sqrt{\Delta_q^2 + \mu_q^2} - \mu_q \right) \right] - \frac{m a^2}{\sqrt{6}} \ln \left( \sqrt{\Delta_q^2 + \mu_q^2} - \mu_q \right),$$

where we drop the $\Omega$ subscript entirely as it is understood to be zero. The action is a real number, confirming that the condensed phase is stable in time. We will now obtain the grand potential through the standard formula $\Phi = -T \ln Z$, the gap $\Delta_q$, and the chemical potential that promote a platform for our future analysis and allow us to compare to standard results.

**Grand potential** The grand potential $\Phi_q$ is obtained directly from the action

$$\Phi_q = -\frac{m L^2}{4\pi} \left[ \mu_q \left( \sqrt{\Delta_q^2 + \mu_q^2} - \mu_q \right) \right] - \frac{m a^2}{\sqrt{6}} \ln \left( \sqrt{\Delta_q^2 + \mu_q^2} - \mu_q \right).$$

As expected, the grand potential tends to that of the normal state when $|\Delta_q| = 0$. In 3D the form of the grand potential similarly mirrors the 3D action without a factor of $\beta$.

A subtlety that bears mention is that in both 2D and 3D the expression above requires $q^2/2m < |\Delta_q|^2/\mu$, that is when the additional kinetic energy of a Cooper pair is less than the condensation energy. Above that limit, the additional kinetic energy is sufficient to break the Cooper pairs and so the grand potential evaluates to zero identically.

**Superconducting gap** The gap is determined by requiring that the grand potential be stationary with respect to the gap, $\frac{\partial \Phi_q}{\partial \Delta_q} = 0$, giving the gap

$$\Delta_q = \begin{cases} \frac{1}{m \alpha} \sqrt{1 + 2m a^2 \mu_q} & q < \frac{2}{\alpha} \\ 0 & q \geq \frac{2}{\alpha} \end{cases}.$$ (6)

The gap in 3D meanwhile is the solution of the implicit equation

$$-\frac{1}{k_F a} = \frac{2}{\pi} \sqrt{\frac{\mu_{q}^{(3D)}}{F_{c}}} I_2 \left( \frac{\Delta_{q}^{(3D)}}{\mu_{q}^{(3D)}} \right),$$ (7)

where $I_2(z) \equiv \int_0^\infty dx x^2 \left( \sqrt{x^2 + (x^2 - 1)^2} - (x^2 - 1) - 2^2/2^2 \right)$.

**Solving for $\mu$** The chemical potential $\mu$ is found from the equation $N = -\partial \Phi_q / \partial \Delta_q$. In 2D it is then

$$\mu = F_{c} \left( 1 - \frac{1}{k_F a^2} + \frac{q^2}{4k_F^2} \right),$$

and that depends on the net momentum of the condensed Cooper pairs, owing to their kinetic energy.

In 3D we recast the BCS number equation [25] to obtain

$$1 = \frac{3}{2} \sqrt{\frac{\mu_{q}^{(3D)}}{F_{c}}} I_3 \left( \frac{\Delta_{q}^{(3D)}}{\mu_{q}^{(3D)}} \right),$$ (8)

where $I_3(z) \equiv \int_0^\infty dx x^2 \left[ 1 - (x^2 - 1)/\sqrt{x^2 + (x^2 - 1)} \right]$. Since the pair of coupled Eqns. (7) and (8) only depend implicitly on $q$ through $\Delta_q^{(3D)}$ and $\mu_q^{(3D)}$, we conclude that $\mu_q^{(3D)} = \mu_{BCS}^{(3D)}$ and therefore $\mu^{(3D)} = \mu_{BCS}^{(3D)} + q^2/2m$. At $q = 0$ the forms of Equations (7) and (8) are indeed equivalent to those of the regularized BCS equations [25].

**Weak interactions** We study the weakly interacting limit in 2D by setting $k_F a \gg 1$. In this limit, $\mu_q \approx F_{c}$ as expected and the gap reduces to $\Delta_q \approx 2F_{c}/k_F a$ from which we may extract the 3D analogue $\Delta_q^{(3D)} \sim F_{c} e^{-\pi/2k_F a}$ by inspection of the regularisation procedure in Eq. (3), which agrees with standard BCS theory [25]. Similarly, we can state that in the weakly interacting limit the validity requirement $q^2/2m < |\Delta_q|^2/\mu$ takes the form $q < \frac{8F_{c}}{\mu} e^{-\pi/2k_F a}$. 

3
3.2 Oscillating single channel

When \( \Omega \) is nonzero, the action \( S_{q, \Omega} \) is complex. Expanding the 2D expression of Eq. (4) in small \( \Omega \) about our static \( \Omega = 0 \) solution, we obtain

\[
S_{q, \Omega} = S_{q, 0} - \frac{\beta m L^2}{4 \pi} \left( \sqrt{|\Delta_q|^2 + \mu_{q, 0}^2} - \mu_{q, 0} \right) \Omega + \mathcal{O}(\Omega^2).
\]

As \( S_{q, 0} \) is real, the imaginary part of \( S_{q, \Omega} \) is linear in \( \Omega \). All terms of order \( \Omega^2 \) and higher are proportional to at least the second power of \( |\Delta_q| \). The imaginary part of the action corresponds to the spontaneous decay rate of Cooper pairs condensed in this superconducting channel, \( \Gamma_{q, \Omega} = \frac{|\Delta_q|^2}{2m} \). In 3D, the action may be likewise expanded in the low-\( \Omega \) limit to obtain an imaginary part of the action linear in \( \Omega \).

In this section we have decoupled in a single channel, performing a BCS-like analysis of the resulting simplified action for general pair momentum \( q \) and frequency \( \Omega \). Two broad conclusions follow from this analysis. Firstly, when \( \Omega = 0 \), multiple \( q \) channels are stable with identical nonzero gap magnitude and equal grand potential. This should be observable in weakly interacting superconductors and can be understood as the system admitting a persistent supercurrent, provided the pair moves slowly enough that dissipation through quasiparticle excitation is not energetically feasible. Secondly, for \( \Omega \neq 0 \), the action develops an imaginary term, limiting the lifetime of oscillating modes. This may be thought of as an inductance that promotes stability of gap-dependent macroscopic observables, such as the supercurrent.

4 Multiple channels

The results of the previous section indicate that in principle, multiple channels are stable at any particular scattering length, which naturally begs the question of whether multiple channels coexist in the ground state. Such communal superconductivity has previously been analyzed and explored numerically in spin-imbalanced systems [19, 20] and so it is natural to now look at spin-balanced systems. We will introduce the variational freedom to explore these multiple active channels with the communal parameter \( N_q = \sum_q \), the number of \( q \) channels with nonzero gap. Clearly, \( N_q \) is at least equal to 1 (standard BCS superconductor) and is bounded from above by one of two physical arguments that in 2D take the form

\[
N_q < \min \left( 1 + \frac{2N}{k_F \alpha^2}, \frac{N}{2} \right),
\]

where the first limit (weakly interacting) corresponds to all superconducting channels for which \( q < 2/a \) active and is exactly equivalent to the physical limit \( q^2/2m < |\Delta_q|^2/\mu \) mentioned previously, with the second limit (strongly interacting) that there are only \( N/2 \) choices of pairing partner for each fermion. The crossover is at \( k_F a = 2 \). We note for completeness that in 3D the first limit has the form \( N_q = 1 + N \max_{a}(a)^3/2k_F^3 \) where \( \max_{a}(a) = \sqrt{2m/|\mu|} |\Delta_q(a)| \) and the second limit is unchanged.

In addition to this new communal variational freedom, we will also consider the effect on the grand potential of the short-lived finite \( \Omega \) modes, where quantum fluctuations of the temporally oscillating modes can contribute to driving communal ordering of the superconducting gap. This contribution will then be added to a minimal model of multiple active static \( \Omega = 0 \) modes. We therefore calculate the total quantum partition function as \( Z = Z_0 Z_{\Omega \neq 0} \), where \( Z_0 \) gives the multi-channel saddle point approximation and \( Z_{\Omega \neq 0} \) accounts for temporal fluctuations of the various modes. The partition function allows us to find the grand potential and differentiate to obtain the expected value of the number of fermions shared between Cooper pairs, \( N_q \), and then explore the evolution of \( N_q \) as we approach the BEC-BCS crossover. We tackle the static and fluctuating contributions in order.

4.1 Static channels

We first focus on the static \( \Omega = 0 \) channels. The static part of the partition function has the form

\[
Z_0 = \exp \left[ -\beta \frac{1}{N_q} \sum_q \Phi_q(|\Delta_q|, \mu) \right],
\]

which accounts for the long-lived, \( \Omega = 0 \) channels where a \( |\Delta_q, \mu| \neq 0 \) mean-field solution is possible. The channels are coupled as they draw from the same reservoir of fermions with common chemical potential \( \mu \). The averaging over modes may be understood in the context of the quantum action as considering each fermion as being paired to multiple opposite-spin fermions probabilistically, and all channels are equally weighted since the grand potential of each channel in the single channel decoupling is identical. The mean-field grand potential is then

\[
\Phi_0 = \frac{1}{N_q} \sum_q \Phi_q(|\Delta_q|, \mu) = -\frac{E_F L^2 (1 + 2ma^2 \mu)}{4\pi k_F^3 a^4} + E_F (N_q - 1)^2 \frac{1}{4N_q k_F^3 a^2},
\]

that is, a sum over the grand potentials of single channel superconductors. The contribution from oscillating channels does not depend on the magnitudes of the static channels and so we may find the superconducting gap in the same way as for the single channel, by requiring that \( \Phi_0 \) be extremised. The result is the same as in Eq. (6) except that \( \mu \) is constant, making the gap vary with \( q \) in contrast to the single channel picture where the gap had the same magnitude for all \( q < 2/a \). With the form of the gap, we may then evaluate the sum over \( q \), allowing us to split the energy contributions into the BCS grand potential.
(the first term) and \( N_q \)-dependent communal correction that arises from the changing magnitude of the gap. For the physically realizable values of \( N_q \), the static grand potential is minimized at \( N_q = 1 \), the standard BCS result. We therefore turn to address the contributions from the oscillating channels to determine whether they can drive communal pairing with \( N_q > 1 \).

### 4.2 Finite \( \Omega \) plasma

Having determined the static channel contribution, we may now consider the effect of fluctuations in \( \Omega \neq 0 \) channels. We consider transitions of a Cooper pair from a stable static channel to a spontaneously decaying oscillating channel to obtain the occupation probability of an oscillating channel as \( \Phi_q(\Omega)Q_{q,\Omega}^{\mathrm{sd}} + \Gamma_{q,\Omega}^{\mathrm{sd}} \). The modification to the mean-field partition function accounting for the short-lived excitations is then

\[
Z_{\Omega \neq 0} = 1 + \sum_{q,\Omega \neq 0} \frac{\Phi_q(\Omega)Q_{q,\Omega}^{\mathrm{sd}} + \Gamma_{q,\Omega}^{\mathrm{sd}}}{\Phi_q(\Omega) + \Gamma_{q,\Omega}^{\mathrm{sd}}} \left[ \frac{\Phi_q(\Omega)Q_{q,\Omega}^{\mathrm{sd}} + \Gamma_{q,\Omega}^{\mathrm{sd}}}{\Phi_q(\Omega) + \Gamma_{q,\Omega}^{\mathrm{sd}}} \right]^2 + \ldots
\]

\[= \exp \left[ \sum_{q,\Omega \neq 0} \frac{\Phi_q(\Omega)Q_{q,\Omega}^{\mathrm{sd}} + \Gamma_{q,\Omega}^{\mathrm{sd}}}{\Phi_q(\Omega) + \Gamma_{q,\Omega}^{\mathrm{sd}}} - 1 \right] \quad (12)\]

The 1 accounts for the situation where no such excitations are present, the second term for when a single channel is excited, the third for when two are simultaneously excited and so on.

The form of the grand potential may be taken from Eq. (5) and the spontaneous decay rate from Subsection 3.2. In order to evaluate the sums, it is necessary to express the gap magnitudes explicitly in terms of \( q \) and \( \Omega \). Once again, we extremise the grand potential with respect to \( \Phi_q(\Omega)Q_{q,\Omega}^{\mathrm{sd}} + \Gamma_{q,\Omega}^{\mathrm{sd}} \) to obtain the partition function. The term in the exponential is positive for \( 1 < N_q < 1 + L^2/\pi a^2 \), that is, for all accessible values of \( N_q \), corresponding to an increase in the number of accessible microstates and thus an entropically driven decrease in the grand potential. The presence of temporally oscillating modes thus contributes an entropic term to the grand potential, increasing the number of accessible microstates and thereby reducing the grand potential. Qualitatively similar behaviour may be obtained in 3D.

### 4.3 Optimizing \( N_q \)

With the grand potential in place, we are well-positioned to determine \( N_q \). Combining the static and oscillating contributions of Eq. (11) and Eq. (13) gives \( \Phi \) as a function of \( N_q \), which may then be minimized to obtain the optimal number of stabilised communal pairing channels as

\[
N_q = 1 + \frac{2N}{k^2 \pi^2 a^2} - \frac{\pi(32 + \pi)N}{128(1 + 2ma^2\mu)k^2 a^2} \quad (14)
\]

is a dimensionless function of the dimensionless variable \( x \) characterising the \( N_q \) dependence of this part of the partition function. The term in the exponential is positive for \( 1 < N_q < 1 + L^2/\pi a^2 \), that is, for all accessible microstates and thus an entropically driven decrease in the grand potential. The presence of temporally oscillating modes thus contributes an entropic term to the grand potential, increasing the number of accessible microstates and thereby reducing the grand potential. Qualitatively similar behaviour may be obtained in 3D.

![Fig. 1 Plot of the ratio of \( N_q \) to \( N \) as \( N \to \infty \) as a function of dimensionless interaction strength \( g^* \) in 2D (blue) and 3D (red). In 2D, \(-\frac{1}{g^*} = -\frac{1}{g} \ln(k_F a)\) while in 3D, \(-\frac{1}{g^*} = \frac{3\pi}{8\pi k_F a}\). Interaction strength increases from left to right. The dotted black line indicates the theoretical maximum of \( \frac{N_q}{N} = \frac{1}{2} \).

![Diagram](image-url)
structure, of the superconducting gap means that communal
pairing in spin-balanced systems emerges as or-
der by disorder.

The grand potential in 3D exhibits qualitatively similar
behaviour, favouring $N_q = 1$ if not for the addi-
tion of the temporal fluctuation term, which instead
promotes near maximal $N_q$ provided interactions are
weak, that is $k_F a \to 0$.

The emergence of communal pairing and increase of
$N_q$ is shown in Fig. 1, with $N_q$ increasing smoothly as
a function of the scattering length in both 2D and 3D.
This is a marked difference from BCS theory which
presupposes $N_q = 1$ at all interaction strengths. For
case of comparison, we have chosen to plot $N_q$ as a
function of the dimensionless interaction strength
$q^* = \frac{Nq}{\pi} \frac{\pi}{\lambda}$, where $\gamma_0$ is the inverse of the first term in the
regularisation Eq. (3), so $-\frac{1}{\gamma^*} = -\frac{1}{\pi} \ln(k_F a)$ in 2D
while in 3D, $-\frac{1}{\gamma^*} = \frac{3}{\pi} \ln(k_F a)$. The effect is stronger in 2D
compared to 3D due to fluctuations being stronger in 2D.

4.4 Adding gap fluctuations

We have shown how temporal fluctuations and con-
comitant expansion of the phase space entropically sta-
bilise a communal state. These considerations consti-
tute a nontrivial extension of the original BCS theory
that is nevertheless still a mean-field approach, and is
therefore orthogonal to the usual treatment of Gaus-
sian fluctuations of the order parameter, with which
the T-matrix approach has had much success [12]. It
is therefore instructive to consider both sources of or-
thogonal fluctuation simultaneously by adding the dif-
ference between our obtained communal results and
the traditional BCS mean field to the T-matrix results.

This is shown in Fig. 2 where we have plotted inter-
nal energy per particle against the interaction param-
eter $\ln(k_F a)$. The BCS mean field result is constant
at 0.5, as seen by the dashed line, while the effects of
Gaussian fluctuation of the order parameter obtained
via the T-matrix approach are shown by the dotted-
dashed line and are seen to consistently overestimate
the energy calculated by quantum Monte Carlo meth-
ods [29, 30, 31, 32]. This disparity has previously been
postulated as the GMB effect or beyond-quadratic
fluctuations of the order parameter [12]. Adding our
correction to the T-matrix results gives the solid line
which comes closer to the Monte Carlo results partic-
ularly around $\ln(k_F a) \approx 2$. Furthermore, the quantum
Monte Carlo results are more reliable in the interme-
diate interaction regime than the weakly interacting
regime as the superconducting correlation length be-
comes smaller than the simulation cell length, making
a correction in this intermediate regime particularly
significant. We therefore contend that communal ef-
tects too may play an important role in the ground
state.

The inset of Fig. 2 shows the same bare and
communal corrected T-matrix results over the same
range of $\ln(k_F a)$ as in [12], where we see that at strong
interactions our results greatly deviate from estab-
lished results. This overshoot at $\ln(k_F a) < 2$ is due
to the aforementioned breakdown of assumptions at
high interaction strength, and the system is now more
correctly described as a weakly interacting 2D Bose
gas [12].

4.5 Connection to BEC-BCS crossover

The increase in extent of communal pairing $N_q$ and
concomitant width of the gap in momentum space with
increasing interaction strength points to a connection
between communal superconductivity and the BEC
state. The communal pairing state comprises many
tightly bound, spatially localised Cooper pairs whose
corresponding gap parameter is spread out in moment-
um space, analogous to the BEC state that comprises
many tightly bound pairs of fermions. To probe this connection, we look to the chemical potential. Following the prescription of Subsection 3.1, we solve for $\mu$ and obtain

$$\frac{\mu}{E_F} = 1 - \frac{1}{k_F^2 a^2} - \frac{8}{3\pi k_F^2 a^3} + \mathcal{O} \left( \frac{1}{k_F^2 a^5} \right).$$

The first two terms are the BCS solution so the communal pairing correction is readily isolated as a reduction of the chemical potential, as seen in Fig. 3. Starting from the non-interacting limit where $\mu = E_F$ as predicted by both BCS and communal pairing theory, as interactions get stronger $\mu$ decreases more quickly in communal pairing theory than in traditional pairing theory. The trends established in the communal state points towards a smooth evolution into the BEC regime, with a smooth confinement of more Cooper pairs with tighter spatial extent. The reduction of chemical potential persists even when incorporating the T-matrix analysis.

This variation of chemical potential with interaction strength may be verified directly by experiment, for example by considering the radius of a trapped ultracold atomic gas. In the local density approximation, the chemical potential $\mu$ and density $n$ are related by $\mu \propto n^\gamma$ for some positive $\gamma$ [25] and so the radius of the trapped gas $R$ is where the local chemical potential vanishes, $\mu(R) \equiv \mu - V(R) = 0$ where $V(r)$ is the trapping potential. The radius of the trapped gas is thus a direct measure of the chemical potential by the relation $R \propto \sqrt{\mu}$. The full variation is shown in Fig. 4 where we see the change in radius is significant and should be readily observable in a cold atom gas. While the figure shows that our results indicate a collapse of the gas to a point at $\ln(k_F a) \approx 0$, this occurs beyond the region of validity of our theory and is not expected to be experimentally observed.

5 Discussion and conclusions

We have demonstrated the importance of communal corrections to the BCS theory by increasing variational freedom to include multiple superconducting modes. Partial occupancy of the temporally oscillating modes drive communal ordering of the superconducting gap, with each nonzero gap mode corresponding to a Cooper pair of net momentum $\mathbf{q}$ variationally lowering the grand potential, resulting in a favouring of multiple nonzero gap modes. Widening of the gap in momentum space, and the concomitant confinement of the Cooper pairs in real space with increasing interaction strength, points to a connection between communal superconductivity and the BEC-BCS crossover. Fluctuations of the gap itself were incorporated through the T-matrix analysis [12] resulting in a favourable comparison of the system energy with quantum Monte Carlo results.

The analysis focuses on how the partial occupancy of the temporal oscillating superconducting gap modes drive the emergence of communal order. This partial occupancy is driven by quantum fluctuations, that is by the uncertainty principle rather than temperature and so persist down to zero temperature where they affect the structure of the gap. We neglected the effect of density fluctuations that result in the GMB correction [21, 22, 33, 34, 35, 36] as it simply decouples from the superconducting analysis and reduces the superconducting gap [21, 33, 34]. Magnetic fluctuations were neglected as these are small in spin-balanced systems.

A significant experimental consequence of communal pairing is the variation of chemical potential with scattering length, which may potentially be observed in the radius of trapped cold gases. In addition, other experimental techniques such as radio-frequency spectroscopy [37, 38] that can directly probe the chemical potential. This reduction of the chemical potential compared to the BCS prediction may contribute to the persistent overestimation of the chemical potential by numerical methods compared to direct experimental measurements, such as those by the Jochim group [39], with the magnitude of this mismatch being particularly well described by communal pairing theory near the unitarity limit of $\ln(k_F a) \approx 1$, where interactions are sufficiently strong for effects to be visible beyond experimental uncertainty but still within the range of validity of the theory presented.

Another possible experimental signature is that the spatial structure of the superconducting gap should change with the scattering length, from isotropic in the weakly interacting limit to strongly confined in real space as interactions get stronger and the system approaches the BEC limit. This may be investigated in cold atomic gases, where control of the scattering length is well established [37, 38, 40], for example using angle-resolved photoemission spectroscopy [41]. The momentum-space structure of the gap could also be probed directly using Bogoliubov quasiparticle interference imaging [42]. In 2D, the analysis predicts that
the superconducting gap has a width in momentum space that is inversely proportional to the scattering length, \( q_2D = \frac{2}{a} \) at weak interactions with \( k_F a < 2 \). In 3D, for weak interactions \( k_F a \to 0^- \), the width is predicted to follow \( q_{(3D)} \propto k_F e^{\pi/2k_F a} \). However, we have demonstrated that low dimensionality promotes a higher \( N_q \) and so the experimental verification might be more straightforward in 2D systems. The additional pairing channels may also be visible through a range of retroreflected hole momenta in Andreev reflection experiments.
