ABSTRACT

Recent measurements showed that the period derivative of the ‘high-$B$’ radio pulsar PSR J1734−3333 is increasing with time. For neutron stars evolving with fallback discs, this rotational behaviour is expected in certain phases of the long-term evolution. Using the same model as employed earlier to explain the evolution of anomalous X-ray pulsars (AXPs) and soft gamma-ray repeaters, we show that the period, the first and second period derivatives and the X-ray luminosity of this source can simultaneously acquire the observed values for a neutron star evolving with a fallback disc. We find that the required strength of the dipole field that can produce the source properties is in the range $10^{12}−10^{13}$ G on the pole of the neutron star. When the model source reaches the current state properties of PSR J1734−3333, accretion on to the star has not started yet, allowing the source to operate as a regular radio pulsar. Our results imply that PSR J1734−3333 is at an age of $\sim 3 \times 10^2-2 \times 10^3$ yr. Such sources will have properties like the X-ray dim isolated neutron stars or transient AXPs at a later epoch of weak accretion from the diminished fallback disc.

Key words: accretion, accretion discs – stars: neutron – pulsars: individual: PSR J1734−3333.

1 INTRODUCTION

The discovery of several new classes of isolated neutron stars, namely the anomalous X-ray pulsars (AXPs) and soft gamma-ray repeaters (SGRs), the X-ray dim isolated neutron stars (XDINs), the compact central objects in certain supernova remnants and the rotating radio transients, has brought into focus the question of possible evolutionary links (see, e.g., Popov 2008; Kaspi 2010). The existence of radio pulsars with large inferred dipole magnetic moments, close to, and in fact partially overlapping with, the range of magnetar fields inferred for AXPs and SGRs ($\gtrsim 10^{14}$ G), and the observation of radio pulses from some AXPs and SGRs further highlight the possibility of links and raise questions about the similarities and differences among these sources. The locations and evolutionary tracks of pulsars in the $P–\dot{P}$ diagram hold the keys to deciphering the links. The recent measurement of the peculiar braking index $n = 0.9 \pm 0.2$ of PSR J1734−3333, the lowest among the measured braking indices of young pulsars, with period $P = 1.17$ s and period derivative $\dot{P} = 2.28 \times 10^{-12}$ s$^{-1}$ (Espinoza et al. 2011) is an exciting new clue.

Analysing the $P–\dot{P}$ diagram of all isolated pulsars in terms of evolution by rotationally powered dipole radiation into the vacuum, starting with the initial rotation rate and the magnetic dipole moment at birth, and assuming that the dipole moment remains constant, fails to explain the distribution of all young pulsars on the $P–\dot{P}$ diagram or to shed light on the possible connections of the distinct classes. Evolution of the magnetic dipole moment and its angle with the rotation axis is one direction of extending the picture, as suggested in the work reporting the braking index of PSR J1734−3333 (Espinoza et al. 2011). Magnetic field evolution and amplification leading to magnetar strength ($10^{14}−10^{15}$ G) surface fields have been invoked to explain the bursts of SGRs and AXPs (Duncan & Thompson 1992). This does not require that the magnetar strength fields be necessarily in the dipole component that controls the spin-down of the pulsar and thereby its evolution on the $P–\dot{P}$ diagram. Indeed, the recently published $\dot{P}$ upper limit of SGR 0418+5729 (Rea et al. 2010) has shown that the surface dipole field of this pulsar is at most $7.5 \times 10^{12}$ G at the equator ($1.5 \times 10^{13}$ G at the poles). This has been interpreted in terms of the decay of the magnetar dipole moment of this SGR (Turolla et al. 2011). All measured braking indices (Becker 2009) deviate from the $n = 3$ value, characteristic for dipole radiation in vacuum. Braking indices $n < 3$ imply a growing magnetic dipole moment (or growth of the dipole moment component perpendicular to the rotation axis). Thus, to understand the behaviour of pulsars and magnetars in different parts of the $P–\dot{P}$ diagram requires growth, or decay, of the magnetic dipole moment perpendicular to the rotation axis, at rates depending on the sources.

An alternative avenue for a more general picture of isolated pulsar evolution is to allow for the possibility of interaction with matter around the star, so that the emission is not dipole radiation in...
vacuum. An effective possibility is that some matter left over from the supernova explosion is actually bound to the neutron star, in the form of a ‘fallback’ accretion disc, as it necessarily carries angular momentum, as proposed by Chatterjee, Hernquist & Narayan (2000) to explain the properties of AXPs. Alpar (2001) suggested that the presence or absence, and the initial mass, of a fallback disc could be the third initial condition, complementing the initial rotation rate and dipole magnetic moment, to determine the subsequent evolution of different classes of neutron stars. A first simple application of this idea to pulsar braking indices and motion across the $P – P$ diagram was presented by Alpar, Ankay & Yazgan (2001). Discoveries of radio pulsars with long periods and large period derivatives suggested that these sources could have evolutionary links with AXPs and SGRs (Kaspi 2010; Espinoza et al. 2011; see, e.g., Mereghetti 2008 for a recent review of AXPs and SGRs).

In this paper, we apply the fallback disc model (FDM) in detail to the evolution of PSR J1734–3333 and show that the model can explain all the properties of this source, including its braking index. In Section 2, we outline the model and examine evolutionary tracks for a neutron star with a fallback disc to search for scenarios leading to the present properties ($P$, $P$, and $L_\nu$) of PSR J1734–3333. We trace all possible initial conditions, namely the initial period, dipole field and disc mass, that can produce the source properties. We discuss the results of our model calculations in Section 3, and summarize our conclusions in Section 4.

2 THE MODEL

In the FDM (Chatterjee et al. 2000; Alpar 2001) the period and luminosity evolution are determined by the interaction between the neutron star and a fallback disc that orbits it. The mid-infrared detections from the AXPs 4U 0142+61 (Wang, Chakrabarty & Kaplan 2006) and 1E 2259+586 (Kaplan et al. 2009) are consistent with the presence of fallback discs around these sources (Ertan et al. 2007). It was shown by Ertan & Çalışkan (2006) that the observed near-IR luminosities and the upper limits of AXPs/SGRs are compatible with the expectations of FDM. The values of the dipole field strength at the pole of the neutron star $B_0$, indicated by FDM fits to optical/IR data of 4U 0142+61 (Ertan et al. 2007) and by the results of the work explaining the long-term $P$, $P$, and X-ray luminosity, $L_\nu$, evolution of AXPs and SGRs, are less than $10^{13}$ G in all cases (Ertan et al. 2009; Alpar, Ertan & Çalışkan 2011). It was proposed in these papers that the magnetar strength fields needed to power the bursts must be residing in quadrupole and higher multipole components. The higher multipole fields fall off with distance from the star more rapidly than the dipole field does, leaving the dipole field to determine the interaction with the disc and the resulting torques.

The interactive evolution of the neutron star and the fallback disc can have epochs with accretion as well as radio pulsar epochs. The neutron star enters the accretion regime and experiences an efficient torque if and when the inner edge of the fallback disc penetrates into the light cylinder. The neutron star can then spin down to long periods of several seconds on time-scales from $\sim 10^5$ to $\sim 10^7$ yr, depending on the disc torques, the dipole field strength $B_0$, and the disc mass $M_\text{d}$. The first (ejector) phase of evolution without accretion could last from several years to more than $10^7$ yr depending on $B_0$, $M_\text{d}$ and initial period $P_0$. During this phase, the neutron star is a radio pulsar. In this work, we show that PSR J1734–3333 is likely to be in the radio pulsar phase without accretion at present and that the accretion epoch could start at a future time. In the accretion phase, at a time depending on the initial parameters, the inner disc will reach the light cylinder and the accretion will stop. After the accretion phase, the disc could remain attached to the light cylinder and the disc torque could still remain active while its efficiency gradually decreases to the level of the dipole radiation torque. Unlike a steady-state disc in a binary, where the accreting stage can be sustained on the evolutionary time-scales of the binary and the companion, the fallback disc around an isolated neutron star will diminish. From the beginning, the outermost parts of the disc are always at low temperatures. Eventually, temperature even in the inner disc becomes too low to sustain viscosity. The disc then becomes passive, mass inflow and disc torques terminate. The decreasing luminosity and disc torque together lead to the observed period clustering (see Ertan et al. 2009 and Alpar et al. 2011 for details).

For PSR J1734–3333, we investigate the evolution mainly in the initial radio pulsar phase. We address the peculiar braking index of PSR J1734–3333, thereby exploring the effect of a possible fallback disc on the evolution of isolated radio pulsars across the $P – P$ diagram. The recent measurement of the second derivative of the period, $P = 5.3 \times 10^{-24}$ s$^{-2}$ (Espinoza et al. 2011), provides an opportunity to test FDM evolutionary scenarios more stringently than before, checking for the first time for simultaneous agreement of $P$ with $P$, $P$ and X-ray luminosity, $L_\nu$. The X-ray luminosity of the source is $7.3 \times 10^{31}$–$6.6 \times 10^{32}$ erg s$^{-1}$, taking into account the 25 per cent error margins for the distance estimate (Olausen et al. 2013). It is interesting that the $P$ of PSR J1734–3333 is positive. This means that the pulsar is evolving towards the upper right corner, the AXP/SGR region, of the $P – P$ diagram. For an isolated neutron star evolving by magnetic dipole radiation in vacuum, this would require a dipole field growing in time. Note that the toroidal and dipole fields of AXPs/SGRs, starting from the early phase of evolution, should decrease rather rapidly with time in the magnetar model (see, e.g., Turolla et al. 2011).

The model we employ for PSR J1734–3333 is the same as the one we used to investigate the long-term evolution of AXPs/SGRs in our earlier work. The details of the model are described in Ertan et al. (2009) and Alpar et al. (2011). We start with an initially extended disc with an inner radius equal to the Alfvén radius

$$r_A = (GM)^{1/7} \mu^{4/7} M_\text{in}^{-2/7},$$  

(1)

where $M_\text{in}$ is the rate of mass flow arriving at the inner disc, $G$ is the gravitational constant, $M$ and $\mu$ are the mass and the magnetic dipole moment of the neutron star, respectively. When the inner disc radius $r_\text{in}$, calculated by equation (1), exceeds the light cylinder radius $r_\text{LC}$, we set $r_\text{in} = r_\text{LC}$ (Alpar et al. 2011). This assumes that the inner disc remains linked on the closed field lines when it cannot enter the light cylinder. In this phase, accretion is not possible, and pulsed radio emission is allowed. In the phase of spin-down with accretion, when the inner disc is inside the light cylinder and greater than the corotation radius ($r_\text{co} < r_\text{in} < r_\text{LC}$), a fraction of the matter could be expelled from the system while the remaining fraction accretes on to the neutron star.

In the accretion phase, we calculate the disc torque acting on the neutron star using

$$N = \frac{1}{2} M_\text{in} (GM r_\text{in})^{1/2} (1 - \omega_1^2) = I \Omega_1,$$  

(2)

(Ertan & Erkut 2008), where $I$ is the moment of inertia of the neutron star. The fastness parameter is defined as $\omega_1 = \Omega_1 / \Omega_1 (r_\text{in})$, where $\Omega_1 (r_\text{in})$ is the angular frequency of the disc at $r_\text{in} = r_\text{in}$ and $\Omega_1$ is the angular frequency of the neutron star. Using equations (1) and (2), it is found that $P \propto B^{-2}$, independent of $M$ and $P$ when the system is
not close to rotational equilibrium. This indicates that $P$ is constant and $P = 0$ in this phase. When a high-luminosity AXP/SGR is approaching (or receding from) rotational equilibrium, $\dot{P}$ is negative (positive). In the early radio phase, the magnetic dipole radiation torque could dominate the disc torque for fast-born pulsars ($P_0 \lesssim 50$ ms) for $B_0 \sim 10^{12}$ G. We calculate the total torque including also the magnetic dipole torque $N_{\text{dip}} = -\frac{2\mu^2\Omega_1^2}{3c^3}$.

In our model calculations, we find that over the spin history of PSR J1734–3333, the dipole radiation torque remains two to three orders of magnitude weaker than the disc torque for an initial period of $P_0 \sim 300$ ms. For a given field strength, the ratio of the torques depends on the chosen disc torque model and the initial period $P_0$. For instance, our results agree with the results of Yan, Perna & Soria (2012), who found that for slow-born pulsars (with $P_0 \sim 300$ ms) the disc torque dominates for the first $\sim 10^5$ yr. In their model, for fast-born pulsars ($P_0 \sim 5$ ms), the dipole torque is the dominant mechanism for the first $\sim 10^9$ yr. The disc torque we employ in our model is more efficient than that used in Yan et al. (2012), and depending on the disc mass, it could start to dominate the dipole torque in an earlier phase of the evolution for fast-born pulsars [which probably represent a small set among newborn neutron stars, lying in the tail of a Gaussian distribution with mean 300 ms and standard deviation 150 ms, according to the simulations of Faucher-Giguère & Kaspi (2006)].

The mass-flow rate at the inner disc is calculated at each evolutionary step by solving the diffusion equation with an initially thin disc surface density profile (e.g. Ertan et al. 2009). Initially, for numerical reasons, we set the outer disc radius at $r_{\text{out}} = 5 \times 10^{14}$ cm. After the first time step, $r_{\text{out}}$ has a dynamical evolution such that the temperature at $r_{\text{out}}$ remains equal to $T_y$, and beyond this radius the disc is assumed to be in a viscously inactive phase. Because of decreasing irradiation flux, temperatures and $r_{\text{out}}$ also decrease gradually with time. The initial disc mass is found by integrating the initial surface density profile. Since the position of the initial outer disc radius is not well known, our $M_{\text{d}}$ values may not reflect the actual full disc mass. In this phase, we substitute $r_{\text{in}} = r_{\text{LC}}$ to calculate the disc torque (equation 2). When the dipole torque is negligible, we find $\dot{P} \propto M_{\text{d}} P^{7/2}$ in this phase. We perform numerical calculations to follow the evolution of $M_{\text{d}}$ together with corresponding $P$, $\dot{P}$ and $P$ at each time step (Ertan et al. 2009; Alpar et al. 2011). We repeat the calculations until we identify the initial conditions that can produce the observed $P$, $\dot{P}$ and $P$ and also, in the present case, $L_x$ of PSR J1734–3333 simultaneously, at an age when the disc does not penetrate the light cylinder, allowing for radio pulsar activity.

In the radio pulsar phase, for a neutron star with the properties of PSR J1734–3333 the source of the X-ray luminosity is very likely to be the cooling luminosity. For the fast-born pulsars, the dipole radiation luminosity could remain well above the cooling luminosity until the periods increase to a few 100 ms. We include the cooling and dipole luminosities in addition to dissipation due to magnetic and disc torques (Alpar 2007) in the calculation of the total luminosity in the radio phase. In the long-term evolution of AXPs/SGRs and XDINs, when the sources reach long periods of a few seconds, the presence of cooling luminosity extends the lifetime of the disc by providing irradiation even in the absence of accretion luminosity. During the initial radio phase, it does not have a significant effect on the evolution, but, through the effect of irradiation on the disc evolution and disc torques, it affects the time at which the model source acquires the observed rotational properties ($P$, $\dot{P}$, $P$) simultaneously. In our model, we employ the intrinsic cooling luminosity evolution calculated by Page, Geppert & Weber (2006) with the assumption of an isothermal neutron star with radius 12 km and mass 1.4 $M_\odot$. The results are not sensitive to the choice among standard cooling scenarios.

3 RESULTS AND DISCUSSION

The model curves that can account for the properties of PSR J1734–3333 are seen in Figs 1–4. Performing many simulations tracing the initial conditions, we obtain reasonable results for the range of disc masses $M_d = 9.0 \times 10^{-6} - 1.5 \times 10^{-5} M_\odot$ and for dipole fields with $B_0 = 9 \times 10^{11} - 1 \times 10^{13}$ G. The model is in very good agreement with $P$, $\dot{P}$, $P$ and $L_x$ of the source with $B_0 \simeq 2 \times 10^{12}$ G (solid curve in Fig. 1). For the solid curve in Fig. 1, the disc mass $M_d = 3 \times 10^{-7} M_\odot$ and the initial period $P_0 = 300$ ms.

![Figure 1. Evolution of the luminosity, period, first and second period derivatives of the model sources. The horizontal lines show the properties of PSR J1734–3333, with the observational uncertainties in $L_x$ and $P$. The vertical lines show the time period over which the solid (red) model curve traces the uncertainty range of $P$. Values of $B_0$ are given in the second panel. For these calculations, we have taken $M_d = 3 \times 10^{-7} M_\odot$ and $P_0 = 300$ ms. In the accretion phase, sources enter the constant $\dot{P}$ phase and $\dot{P}$ becomes 0 (see the text for details).](https://academic.oup.com/mnras/article-abstract/431/2/1136/1446431)
On the evolution of the radio pulsar PSR J1734−3333

Figure 2. Evolution of the luminosity, period, first and second period derivatives of model sources. The horizontal dotted lines represent the properties of PSR J1734−3333 with the range of uncertainties in $L_x$ and $\dot{P}$. These illustrative model curves are obtained for $B_0 = 2 \times 10^{12} \text{G}$. The values of initial period and disc mass are given in the second panel. The cooling luminosity is shown with the dot-dot–dashed (black) curve. It is seen that the source properties could be well reproduced with different initial periods. Between the vertical lines given with the same colour, the model sources trace the uncertainty range of $\dot{P}$ (see the text for details).

In Fig. 1, we also present illustrative model curves (dashed and dot-dashed) that cannot represent the evolution of PSR J1734−3333. For the viable model in Fig. 1, and all three viable models shown in Fig. 2, the source is powered by intrinsic cooling when the observed properties of PSR J1734−3333 are attained. For this radio pulsar, considering all reasonable model curves, the simultaneous agreement with all these model parameters leads to a model estimate of the present age of $\sim 3 \times 10^4$ yr. At an epoch later than the present age of PSR J1734−3333, the disc eventually penetrates the light cylinder. Accretion then starts, and the star enters a constant $\dot{P}$ phase. This is also observed as a small abrupt rise in the luminosity curve. There is no substantial increase in the luminosity when accretion starts, because the mass-flow rate has already decreased to low levels by the time the inner disc penetrates the light cylinder. Reasonable model curves indicate that accretion will start at a future time of the order of $\sim 10^4$ yr from the present. For other model source histories, accretion can start at earlier times and the accretion luminosity can be orders of magnitude greater than the cooling luminosity. Evolutionary curves for such models do not simultaneously produce all the observed properties of PSR J1734−3333.

Fig. 1 shows that $\dot{P}$ reaches values of the order of $\sim 2 \times 10^{-22}$ s s$^{-2}$ at the end of the radio pulsar epoch. Before the accretion phase, from $t \sim 10^3$ yr to the present age, the braking index for model sources varies from $\sim 5$ to $\sim 1$. In the accretion phase, $\dot{P} = 0$, $\dot{P}$ becomes constant and the braking index remains $\sim 2$ when the source is not very close to rotational equilibrium.

Figure 3. Evolution of the luminosity, period, first and second period derivatives, for models that do not work for PSR J1734−3333. The horizontal dotted lines show the properties of PSR J1734−3333, with the uncertainties in $L_x$ and $\dot{P}$. These model curves are obtained with $B_0 = 2 \times 10^{12} \text{G}$ and $P_0 = 300 \text{ ms}$. The solid lines are the same as the solid lines in Figs 1 and 2, for the model that works. We also present two illustrative model curves for smaller and greater $M_d$ that cannot represent the evolution of PSR J1734−3333 (see the text for details).
The mass accretion from the disc starts at a time that depends on the initial period \( P_0 \), as well as on \( B_0 \) and \( M_d \) (Ertan et al. 2009). A large range of \( P_0 \) values are allowed for producing the source properties. In Fig. 2, for a given dipole field \( (B_0 = 2 \times 10^{12} \, \text{G}) \), we present three illustrative model curves with initial periods of 50, 100 and 300 ms. To obtain acceptable models, smaller \( P_0 \) values require greater \( M_d \). All model curves given in Fig. 2 produce the X-ray luminosity and the rotational properties of PSR J1734—3333 at different epochs. In the early radio pulsar phase, the source of the luminosity is either the intrinsic cooling or magnetic dipole radiation of the neutron star, depending on \( B_0 \) and \( P_0 \). Reasonable model curves indicate that current luminosity of PSR J1734—3333 is produced by the intrinsic cooling luminosity while the source is slowing down by the disc torques. We find that the rates of dissipation inside the star due to dipole and disc torques (Alpar 2007) do not contribute significantly to the total luminosity in the radio pulsar phase of this source at present. A part of the dipole luminosity is emitted in the X-ray band. For model sources that have low \( P_0 \) and/or high \( B_0 \) values, the dipole radiation could be the dominant luminosity in the early phases of evolution. For instance, for initially fast-rotating model sources with \( B_0 = 2 \times 10^{12} \, \text{G} \), the luminosity of magnetic dipole radiation dominates the intrinsic cooling luminosity until the period increases to beyond \( \sim 200 \, \text{ms} \) (see Fig. 2). For \( B_0 \gtrsim 10^{13} \, \text{G} \), the dipole luminosity remains above the upper limit of the observed luminosity when the rotational properties of PSR J1734—3333 are acquired. We note that the blackbody nature of the X-ray spectrum (Olausen et al. 2013) also indicates that the source of the observed luminosity is likely to be the intrinsic cooling rather than magnetic dipole radiation. For the model sources with \( B_0 \lesssim 9 \times 10^{12} \, \text{G} \), accretion starts before the current rotational properties of PSR J1734—3333 are reached. To sum up, the luminosity, \( P \), \( P \) and \( P \) values of PSR J1734—3333 can be acquired by the model sources only for \( B_0 \) values in the \( \sim 9 \times 10^{11}—1 \times 10^{13} \, \text{G} \) range. The two model curves with the minimum and maximum allowed ranges of these parameters that can produce the properties of PSR J1734—3333 simultaneously.

The important parameters that affect the long-term evolution of the model sources are the initial period \( P_0 \), the minimum temperature of the active disc \( T_p \), which is degenerate with the irradiation efficiency \( C \), (but \( C \) is restricted by optical and IR observations of AXPs; Ertan & Çalışkan 2006), the disc mass \( M_d \), and the dipole magnetic field strength \( B_0 \) on the surface of the star. In our earlier work and in this paper, we take \( T_p \approx 100—200 \, \text{K} \). Since \( T_p \) together with \( C \) determines the end of the active disc phase, they have almost no effect on the evolution during the initial radio phase. The initial period can affect the time of onset of accretion, but similar long-term evolutionary curves could be found for a large range of initial periods. To follow the evolution of model sources in the initial radio phase, there remain only two important parameters: \( M_d \) and \( B_0 \). We repeat the simulations tracing \( M_d \) and \( B_0 \) to find the entire allowed ranges of these parameters that can produce the properties of PSR J1734—3333 simultaneously.

Our results indicate that PSR J1734—3333 could be at an age in the range \( \sim 3 \times 10^4—2 \times 10^8 \, \text{yr} \) depending on the actual initial conditions of the star. For \( B_0 = 2 \times 10^{10} \, \text{G} \) and \( P_0 = 300 \, \text{ms} \), \( M_d = 3 \times 10^{-7} \, \text{M}_\odot \) gives the observed properties of PSR J1734—3333 simultaneously, while for \( P_0 = 100 \, \text{ms} \) the disc mass is \( M_d = 7.3 \times 10^{-8} \, \text{M}_\odot \) and for \( P_0 = 50 \, \text{ms} \) it is \( M_d = 8.5 \times 10^{-7} \, \text{M}_\odot \). For \( B_0 = 2 \times 10^{12} \, \text{G} \) and \( P_0 = 300 \, \text{ms} \), illustrative model curves obtained with different disc masses are given in Fig. 3. The solid (red) curve is the same as the tracks given in Figs 1 and 2 with the same \( B_0 \) and \( P_0 \). It is seen that the model with the greatest \( M_d \) starts the accretion phase earlier, while the source with the smallest \( M_d \) never enters the accretion phase. These models, represented by dashed and dotted-dashed curves in Fig. 3, cannot produce all present properties of PSR J1734—3333 simultaneously.

In later phases of evolution, radio pulsars similar to PSR J1734—3333 are likely to be observed either as transient AXPs in the accretion phase, if they are detected by means of soft gamma-ray bursts, or as XDINs after the termination of the accretion phase, while the disc torques are still effective. We also present the evolution of these model sources on the \( P—P \) diagram in Fig. 5. A paper on the evolution of XDINs is in preparation (Ertan et al., in preparation).

Our long-term evolution model of neutron stars with fallback discs differs from earlier FDMs described in Chatterjee et al. (2000) and Menou, Perna & Hernquist (2001a), as well as Alpar (2001) and Alpar et al. (2001) in two crucial ingredients of the models: (1) the minimum temperature \( T_p \) at which the viscous activity stops and the disc becomes passive, and (2) the torque expression employed in

---

**Figure 4.** Evolution of the luminosity, period, first and second period derivatives, for model sources with the lowest and highest allowed \( B_0 \) values. The magnetic field is given in units of \( 10^{11} \, \text{G} \), the initial period is in seconds and the disc mass is given in units of \( 10^{-8} \, \text{M}_\odot \). The cooling luminosity is shown with the dot-dot-dashed (black) curve.
The evolutionary model curves of the rotational properties of neutron stars and their dependence on mass-flow rate of the disc are sensitive to the disc torque models employed in the calculations. The motivation leading us to the particular torque model employed in earlier work (Ertan & Erkut 2008; Ertan et al. 2009; Alpar et al. 2011) and in this work was the peculiarity of the contemporaneous X-ray luminosity and period evolution of the transient AXP 

XTE J1810−197 in the X-ray enhancement/outburst phase. Nevertheless, the observations of XTE J1810−197 (Gotthelf & Halpern 2007) show that in the range of accretion rates from a few \(10^{13}\) to \(10^{15}\) g s\(^{-1}\), the torque remains almost independent of the mass-inflow rate. We use the same torque model that is in good agreement with this observation, in all subsequent work on spin evolution of neutron stars with fallback discs. This behaviour, observed in XTE J1810−197, cannot be accounted for by earlier disc torque models.

4 CONCLUSIONS

We have shown through a detailed analysis that the observed period, the first and second period derivatives, and the X-ray luminosity of PSR J1734−3333 can be simultaneously reached by a neutron star evolving with a fallback disc. The model is compatible with the pulsed radio emission of the source, since the present source properties are reached at a time when the accretion of matter from the disc is not allowed yet.

The observed properties of PSR J1734−3333 can be obtained at an age of \(\sim 3 \times 10^4\)–\(2 \times 10^5\) yr, with a range of initial periods and with disc masses (\(9 \times 10^{-8} < M_d < 1.5 \times 10^{-6} M_\odot\)), relatively low compared to those estimated for AXPs/SGRs. Dipole fields with strength in the range \(9 \times 10^{11}−1 \times 10^{13}\) G, together with appropriate disc masses and initial periods, give reasonable model curves.

PSR J1734−3333 has not been observed in IR to the best of our knowledge. A search for IR emission from the fallback disc in PSR J1734−3333 will be of great interest. The infrared emission from the disc depends on several factors, like inclination angle of the disc, irradiation efficiency, outer and inner disc radii. We will present elsewhere the expected IR emission from PSR J1734−3333 and sources similar to it in detail, together with a discussion of the assumed parameters.

We expect that PSR J1734−3333 will evolve into the accretion phase within another \(\sim 10^5\) yr (see Figs 1 and 2). By the onset of the accretion phase, the mass-flow rate of the inner disc will have decreased to a very low level such that accretion does not significantly contribute to the total X-ray luminosity. Radio pulsars following evolutionary curves similar to that of PSR J1734−3333 could be detected in the accretion phase if they show soft gamma-ray bursts like AXPs/SGRs – these would be identified as transient AXPs. Such sources are not likely to emit radio waves, having spun down to long periods by this late stage of evolution. Only if they are sufficiently close to Earth, could we detect and identify them as XDINs. Some of these sources could evolve to periods longer than the AXP/SGR periods (Ertan et al. 2009). It is hard to detect them due to low X-ray luminosities. In short, sources like PSR J1734−3333 may evolve to become transient AXPs or XDINS. The evolution of XDINs and their connection with AXPs/SGRs will be the subject of our future work.

ACKNOWLEDGEMENTS

We thank the anonymous referee for his/her useful comments. We acknowledge research support from Sabanci University, from
TÜBİTAK (the Scientific and Technical Research Council of Turkey) through grant 110T243. MAA is a member of the Science Academy, Istanbul, Turkey. We also thank K. Yavuz Ekşi and M. Hakan Erkut for useful discussions.
