Conserved long-range base pairings are associated with pre-mRNA processing of human genes

Svetlana Kalmykova1, Marina Kalinina1, Stepan Denisov1, Alexey Mironov1, Dmitry Skvortsov2, Roderic Guigó3 & Dmitri Pervouchine1

The ability of nucleic acids to form double-stranded structures is essential for all living systems on Earth. Current knowledge on functional RNA structures is focused on locally-occurring base pairs. However, crosslinking and proximity ligation experiments demonstrated that long-range RNA structures are highly abundant. Here, we present the most complete to-date catalog of conserved complementary regions (PCCRs) in human protein-coding genes. PCCRs tend to occur within introns, suppress intervening exons, and obstruct cryptic and inactive splice sites. Double-stranded structure of PCCRs is supported by decreased icSHAPE nucleotide accessibility, high abundance of RNA editing sites, and frequent occurrence of forked eCLIP peaks. Introns with PCCRs show a distinct splicing pattern in response to RNAPII slowdown suggesting that splicing is widely affected by co-transcriptional RNA folding. The enrichment of 3’-ends within PCCRs raises the intriguing hypothesis that coupling between RNA folding and splicing could mediate co-transcriptional suppression of premature pre-mRNA cleavage and polyadenylation.
A double-stranded structure is a key feature of nucleic acids that enables replicating the genomic information and underlies fundamental cellular processes. Many RNAs adopt functional secondary structures, and messenger RNAs (mRNAs) are no exception, although their main role is to encode proteins. In eukaryotes, RNA structure affects gene expression through modulating all steps of pre-mRNA processing, including splicing, cleavage and polyadenylation, and RNA editing. The loss of functional RNA structure has been increasingly reported as implicated in human disease.

To date, a few dozens of functional RNA structures have been characterized in the human genome (Table 1 and Fig. S1). Many of them are formed between evolutionarily conserved regions that are located in introns of protein-coding genes and consist of base pairings spanning thousands of nucleotides. Computational identification of such distant base pairings by de novo RNA folding is not feasible due to a number of technical limitations. However, recent progress in high-throughput sequencing techniques enabled novel experimental strategies to determine RNA structures in vivo. In particular, photo- inducible RNA cross-linking and proximity ligation assays revealed that long-range base pairings are highly abundant in the human transcriptome. Currently, the applicability of these assays for large-scale profiling of RNA structure is still limited, and computational identification of long-range RNA structure remains a great challenge in RNA biology.

Comparative genomics provides a powerful alternative to de novo RNA folding by detecting signatures of evolutionary conservation. Previous reports presented complex methodologies that implement simultaneous alignment and folding to detect RNA elements with divergent sequences that are nevertheless conserved at the secondary structure level. However, a substantial fraction (3.4%) of intronic nucleotides in the human genome are highly conserved at the secondary structure level. Previous reports presented complex methods to identify conserved complementary regions (PCCRs) in pre-aligned evolutionarily conserved regions. In this study, we developed a method named PrePH (PREdiction of PanHands) to efficiently find long, nearly perfect complementary matches in a pair of input sequences, and applied it to all pairwise combinations of CIRs located at a certain distance limit from each other. Subsequently, we analyzed MSAs that had a sufficient amount of variation to detect compensatory substitutions within PCCRs.

Multiple lines of evidence indicate that a large proportion of PCCRs indeed have a double-stranded structure, for example, significant decrease of icSHAPE nucleotide accessibility, high abundance of adenosine-to-inosine (A-to-I) RNA-editing sites, significant overlap with long-range RNA contacts identified by proximity ligation assays, and frequent co-occurrence of the so-called forked enhanced cross-linking and immunoprecipitation (eCLIP) peaks. They also have other characteristic features such as occurrence within introns proximally to splice sites, avoidance of branch points, and obstructive effect on cryptic and inactive splice sites. At the same time, the method has a substantial false-positive rate, which, as we show, cannot be reduced without losing sensitivity to bona fide validated RNA structures (Table 1). The catalog of PCCRs is provided as a reference dataset that is conveniently visualized through a UCSC Genome Browser track. We additionally provide a transcriptome-wide characterization of RNA bridges and exon loop-outs, two particular mechanisms of alternative splicing regulation by long-range RNA structures.

### Results

#### Conserved complementary regions.

To identify conserved complementary regions (CCRs), we considered nucleotide sequences of human protein-coding genes excluding all constitutive and alternative exons, repeats, noncoding genes residing in introns, and other regions with selective constraints that may not be related to base pairings. The remaining intronic regions were characterized in the human transcriptome and the PhastConsElements track of the UCSC Genome Browser, which defines genomic intervals that are highly conserved between 100 vertebrates.

PCCRs were identified in all pairwise combinations of CIR that are located not more than L nucleotides apart from each other and belong to the same gene using PrePH, a k-mer-based method that efficiently predicts long, nearly perfect stretches of complementary nucleotides in a pair of input sequences (see “Methods”). A search for at least 10-nt-long sequences with the hybridization free energy $\Delta G \leq -15$ kcal/mol, minimum helix length $k \geq 5$, and distance limit $L \leq 10,000$ yielded 916,360 PCCRs, on average 75 PCCR per gene, with 95% of genes having not more than 295 PCCRs (Supplementary Data Files 1 and 2). The median free energy of hybridization ($\Delta G$) and the median length of CCRs were $-17.2$ kcal/mol and 13 nts, respectively, with the frequency distribution decaying towards longer and more stable structures (Fig. 1C and Fig. S1A). As expected, longer structures had larger absolute values of $\Delta G$; however, the energy and the length of a PCCR are not directly proportional and the relationship between them depends on the GC content (Fig. S1B, S1C).

### Table 1: Experimentally validated (bona fide) RNA structures in human genes that satisfied PrePH search criteria.

| PCCR i.d. | Gene | Exon | $\Delta G$ | l | d | $E$ value | $s_1$ | $s_2$ | $s_3$ | Ref. |
|-----------|------|------|------------|---|---|---------|------|------|------|-----|
| 98636     | ENAH | Exon 1a | $-19.80$ | 11 | 1728 | 0.4090 | 0.43 | 0.49 | 0.28 | 32  |
| 178925    | SF1  | Exon 10 | $-25.74$ | 14 | 109 | 0.0002 | 0.45 | 0.49 | 0.64 | 28  |
| 739752    | DST  | Exons 46-52 | $-25.00$ | 15 | 9431 | 0.9998 | 0.39 | 0.56 | 0.45 | 29  |
| 883328    | DNM1 | Exons 10a and b | $-25.90$ | 12 | 8864 | 0.2517 | 0.48 | 0.46 | 0.24 | 141 |
| 918502    | PLP1 | Exon 2a | $-15.80$ | 20 | 638 | 0.3871 | 0.24 | 0.71 | 0.36 | 35  |
| 148879    | ATE1 | Exon 7b | $-33.2$ | 17 | 51 | 0.6504 | 0.21 | 0.75 | 0.38 | 36  |
| 148881    | ATE1 | Exon 7a | $-35.9$ | 13 | 952 | 0.5877 | 0.32 | 0.64 | 0.31 | 36  |

$\Delta G$ predicted free energy (kcal/mol), $L$ average length of the two CCRs (nts), $d$ spread (distance between complementary regions, nts), $E$ value $E$ value from R-scape after correction for multiple testing, $s_1$, $s_2$, $s_3$ nucleotide conservation metrics (see “Compensatory substitutions” section).
−30 kcal/mol, which are represented throughout the paper by a uniform color scheme shown in Fig. 1C. To assess the sensitivity of the method with respect to known RNA structures, we collected evidence of functional base pairings in human genes from the literature. All bona fide structures that satisfied the search criteria were successfully found (Table 1 and Fig. S2), while others either did not pass the free energy cutoff, were shorter than 10 nts, located outside of CIR, or did not belong to protein-coding genes (Table S1). Notably, the long-distance intronic interaction that regulates PLP1/DM20 splicing\(^3\) and the RNA bridge in ENAH\(^3\) were both assigned to group I (ΔG = −15.8 and −19.4 kcal/mol, respectively), indicating that less stable structures are not less functional or less interesting than the others. For the purpose of presentation here, we chose the distance limit \(L = 10,000\), which by the order of magnitude corresponds to long-range RNA structures listed in Table 1.

The frequency distribution of the distances between two CCRs in a pair, here referred to as spread, peaks at short distances, decaying towards a non-zero baseline (Fig. S3B). This baseline originates from the distribution of pairwise distances between CIR that were passed to PrePH as an input, which decays towards the same baseline. We next asked whether PCCRs were on average less spread and more stable than PCCRs with insignificant nucleotide covariations (\(E\) value \(\leq 0.05\), \(n = 3204\)) are on average less spread and more stable than PCCRs with insignificant nucleotide covariations (\(E\) value \(\geq 0.05\), \(n = 905942\)); two-sided Mann-Whitney test; *** denotes a statistically discernible difference at the 0.1% significance level.

**Fig. 1 Pairs of conserved complementary regions (PCCRs).** A PCCRs are identified in conserved intronic regions (CIRs) that are <10,000 nts apart from each other. B PrePH computes the dynamic programming matrix based on the precomputed helix energies for all \(k\)-mers (inset) and energies of short internal loops and bulges (see Supplementary Methods for details). C The distribution of PCCR energies consists of four energy groups: group I (−20 < ΔG ≤ −15 kcal/mol), group II (−25 < ΔG ≤ −20 kcal/mol), group III (−30 < ΔG ≤ −25 kcal/mol), and group IV (ΔG ≤ −30 kcal/mol). D The distribution of \(p\), relative position of a PCCR in the gene. E Multiple independent compensatory substitutions support long-range RNA structure in the phosphatidylinositol glycan anchor biosynthesis class L (PIGL) gene. F PCCRs with significant nucleotide covariations (\(E\) value < 0.05, \(n = 3204\)) are on average less spread and more stable than PCCRs with insignificant nucleotide covariations (\(E\) value \(\geq 0.05\), \(n = 905942\)); two-sided Mann-Whitney test; *** denotes a statistically discernible difference at the 0.1% significance level.
distributed uniformly along the gene, or they tend to accumulate in certain gene parts. To quantify the position of a PCCR within a gene, we introduced $p$, a measure of relative position, which changes from 0% for the regions located in the very 5′ end of the gene to 100% for the regions located in the very 3′ end. The metric $p$ can be computed for a PCCR as a whole to represent its relative position, or for each of its CCR separately. The location of PCCR as a whole was not uniform, with two pronounced modes at the 5′ and 3′ end (Fig. 1D). This enrichment was also prominent in the distribution of single CCRs (Fig. S3C), which could be due to stronger evolutionary constraints on the nucleotide sequences at gene ends. Indeed, we found that CCRs exhibit a higher degree of evolutionary conservation than their adjacent regions within CIR (the difference of the average phastCons scores, MW (Mann–Whitney sum of ranks test) test, $p$ value $< 2.2 \times 10^{-15}$) and thus tend to occur in more constrained regions. Gene ontology (GO) terms associated with genes that have PCCRs were enriched with terms related to morphogenesis and development of the central nervous system as compared to genes of the same length, but without PCCRs (Fig. S4).

**Compensatory substitutions.** Compensatory mutations, that is, pairs of nucleotide substitutions that individually disrupt base pairings, but restore them when introduced in combination, play a central role in the evolution of RNA structure. To analyze compensatory mutations in PCCRs, we applied the R-scape program, which scores independent occurrence of complementary substitutions on different branches of the phylogenetic tree, to pairs of multiple sequence alignments (MSAs) that were cut out from the MSA of 100 vertebrates by PCCRs (see “Methods”). The deviation from the null hypothesis that pairwise covariations in a PCCR are not due to conservation of RNA structure was estimated as a product of $E$ values reported by R-scape for all base pairs within the PCCR. These products were adjusted using Benjamini–Hochberg correction.

Out of 916,360 PCCR, for which this computation was possible, only 909,146 had a sufficient number of substitutions to estimate the $E$ value, and only 3204 of them had $E$ value below 5% (Fig. S5). The PCCRs with $E$ value $< 0.05$ were on average more stable and less spread than PCCRs with $E$ value $\geq 0.05$ (Fig. 1F). In some cases, structural alignments were strongly supported by covariations, that is, a highly stable PCCR ($\Delta G = -31$ kcal/mol) spanning 700 nts in the first intron of PIGL gene (Fig. 1E) and PCCRs in the QRICH2 and MRPL42 genes (Fig. S6). However, $E$ values of bona fide RNA structures from Table 1 ranged from 0.0002 for the PCCR responsible for splicing of the intron between exons 9 and 10 in SF1 to 0.0998 for the PCCR associated with exons 46–52 skipping in DST, suggesting that the amount of variation in the nucleotide sequences of PCCRs is generally not sufficient to estimate their statistical significance through compensatory substitutions.

A remarkable feature of standalone RNA regulatory elements is their high level of conservation, as opposed to that of their flanking sequences. We introduced three additional metrics to capture the nucleotide conservation rate within CCR as compared to the background: $s_1$ is the difference between the average phastCons scores within CCR and within 300 nts flanking regions (the larger, the more significant); $s_2$ is the average phastCons score within CCR and 300 nts around it (the smaller, the more significant); $s_3$ is the length of a CCR relative to the length of its parent CIR (the larger, the more significant). However, neither of the three metrics reached extreme values for the base pairings listed in Table 1 (Fig. S7), which indicates that functional PCCRs are not necessarily located in isolated conserved regions and may well occur in a relatively conserved background.

**Support by high-throughput structural assays.** PCCRs represent regions in the pre-mRNA that have an increased capacity to base pair. The propensity of individual nucleotides to base pair was assessed at the transcriptome-wide level by measuring the nucleotide flexibility score with icSHAPE method. We compared the average icSHAPE reactivity within CCR with that in a control set of intervals located nearby (Fig. 2A). Indeed, the average icSHAPE reactivity of nucleotides within CCR was significantly lower as compared to the control (Wilcoxon’s test, $P < 10^{-50}$), and the difference increased by the absolute value with the increase in the structure free energy ($|\beta| = 0.03 \pm 0.01$). However, the icSHAPE reactivity scores were available only for 4551 PCCRs representing 0.5% of the full set. We, therefore, sought for PCCR support in other experimental datasets.

Chemical RNA structure probing can reveal which bases are single- or double-stranded, but it cannot determine which nucleotides form base pairs. We, therefore, validated PCCRs against the long-range RNA–RNA interactions that were assessed experimentally by psoralen analysis of RNA interactions and structures (PARIS) ($n = 15,036$), ligation of interacting RNA followed by high-throughput sequencing (LIGR-seq) ($n = 551,926$), and RNA in situ conformation sequencing (RIC-seq) ($n = 501,144$). Towards this end, we considered the interacting pairs in the experimental data that were located intramolecularly within CIR not $> 10,000$ nts apart from each other, and restricted the set of PCCRs to the underlying CIRs that overlap the experimental dataset (see “Methods”). The precision ($P$) and recall ($R$) metrics were defined as the proportion of PCCRs supported by the experimental method and the proportion of experimental interactions supported by PCCRs, respectively. In addition, we computed $\pi$, the conditional probability of predicting the interacting CCR partner correctly given that another CCR in a pair has been predicted correctly (Table 2).

The best agreement was with respect to the RIC-seq dataset, with precision increasing up to 92% at the expense of decreasing recall when structure stability increased. The $\pi$ metric confirmed that PCCRs tend to correctly identify the interacting partner given that one of the CCRs has been predicted correctly. In addition, we found that free energies of PCCRs supported by RIC-seq and PARIS were significantly lower than those of PCCRs without experimental support (MW test, $\Delta \Delta G \approx 1.2$ kcal/mol, $p$ value $< 10^{-19}$). However, the breadth of these findings is limited by small sizes of the true-positive sets ($n = 1903$ for RIC-seq, $n = 777$ for LIGR-seq, and $n = 969$ for PARIS), because structural assays sparsely cover the transcriptome at cell line-specific conditions and focus on intermolecular interactions.

Finally, we explored how the set of predicted PCCRs relates to a similar list that was reported previously by IRBIS. Unlike PrePH, IRBIS follows the “first-fold-then-align” strategy to simultaneously detect conserved complementarity and sequence homology, but at stricter conditions. Overall, the predictions of the two programs had a large intersection relative to IRBIS predictions indicating that the current method generally outputs a superset of IRBIS predictions both in terms of the number of nucleotides and the number of base pairs (Fig. 2B). The free energies of PCCRs supported by IRBIS were significantly lower than those of other PCCRs (MW test, $\Delta \Delta G \approx 2.7$ kcal/mol, $p$ value $< 10^{-30}$) reflecting the fact that, unlike IRBIS, PrePH allows for short internal loops and bulges. Nevertheless, a small fraction of IRBIS predictions is missing from the list of PCCRs presented here, which relies on the conserved regions from phastConsElements track of the UCSC Genome Browser. Without this limitation, however, the current approach would be impractical from the computational standpoint, and it was our intention to limit the search to conserved regions at the expense...
of losing some structures that are misaligned by structure-agnostic phylogenetic analysis.

**False discovery rate.** One way to estimate the rate of false-positive predictions is to apply the same pipeline that was used to identify PCCRs to a control set of sequences that should not base positive predictions is to apply the same pipeline that was used to

**Splicing.** Previous reports indicate that long-range base pairings are positioned nonrandomly with respect to splicing signals. To elaborate on this, we used the classification shown in Fig. 3A. If a PCCR overlaps an intron, it can be located either entirely within the intron (inside) or the intron can be located entirely outside PCCR (outside), or the two intervals intersect (crossing). The tendency of RNA structure to prefer one of these categories is measured by the enrichment metric, defined as the number of PCCRs in the given category relative to the number of PCCR-like intervals in it. In the previous work, it was described as the so-called "re-wiring" approach. Here, we used the same strategy by running the pipeline on chimeric sets of sequences that were sampled randomly from different genes while controlling for nucleotide composition and length, which confound this comparison (Fig. 2C). The false discovery rate (FDR), defined as the number of predictions in the control set as a fraction of the total number of predictions, depends on PCCR energy, spread, GC content, and E value, ranging from 10% in the most strict to over 50% in the most relaxed conditions (Fig. 2D). As expected, FDR drops with increasing PCCR energy and GC content and with E value. On the other hand, this is a pessimistic estimate since the re-wiring method is known to greatly overestimate the FDR. We, therefore, interpret 47% as an excessively conservative FDR estimate and proceed to the statistical characterization of the full PCCR set with the mindset that at least half of the predictions are true positives.

**Table 2 Precision and recall at different free energy cutoffs (**$\Delta G$**).**

| $\Delta G$ | RIC-seq, $n=1804$ | LIGR-seq, $n=586$ | PARIS, $n=907$ |
|-----------|------------------|------------------|------------------|
|           | PrePH P (%) R (%) $\pi$ (%) | PrePH P (%) R (%) $\pi$ (%) | PrePH P (%) R (%) $\pi$ (%) |
| $-15$     | 1611 52 43 | 362 49 56 | 591 50 51 |
| $-20$     | 364 26 67 | 88 17 58 | 1725 33 60 |
| $-25$     | 84 9 86 | 21 3 48 | 545 14 65 |
| $-30$     | 23 3 91 | 5 1 40 | 160 6 73 |

The precision ($P$) and recall ($R$) are the proportion of PCCRs supported by the experimental method and the proportion of experimental interactions supported by PCCRs, respectively. $\pi$ is the conditional probability of predicting the interacting CCR partner correctly given that another CCR in a pair has been predicted correctly. The column "PrePH" shows the number of PCCRs that satisfy the criteria for comparison. The number of structures in each experimental method is denoted by $n$. The difference between icSHAPE reactivity of nucleotides within CCR and the average reactivity of nearby nucleotides in energy groups I–IV (color code as in Fig. 1C). The linear model $\Delta$reactivity $= \beta_0 + \beta_1 \Delta G$ group is represented by the slanted line; $\beta_1 = -0.03 \pm 0.01$. B Venn diagram for the number of common nucleotides (left), number of common base pairs (middle), and the number of common base pairs among common nucleotides (right) for the predictions of PrePH and IRBIS. C Estimation of the false-positive rate (FDR) by re-wiring, that is, creating a control set that consists of chimeric non-cognate sequences sampled from different genes. D FDR as a function of energy cutoff $\Delta G$ (top left), maximum distance between CIR (top right), $E$ value (bottom left), and GC content (bottom right). Solid lines represent the fitted average over $n=16$ randomizations; shaded areas represent 95% confidence intervals obtained by the locally estimated scatterplot smoothing (LOESS) regression.
be counted more than once if it is located inside one intron and crosses another). In the first control set, referred to as random shift, each PCCR was shifted randomly within its gene. The number of PCCRs inside, outside, and crossing the reference set of intervals (e.g., introns) are counted. B PCCRs are enriched inside introns and depleted in outside and crossing configurations. C PCCRs looping out exons are depleted. D The cumulative distribution of the average exon inclusion rate (Ψ) in HepG2 cell line for exons looped out by PCCRs of the four energy groups vs. exons not looped out by PCCRs (Ctrl). KS denotes the two-sample Kolmogorov-Smirnov test. Sample sizes for energy groups I-IV and control are n = 73,366, 13,974, 1877, 374, and 161,947, respectively. E The distribution of distances from intronic PCCRs to intron ends (bin size 75 nts). Group I PCCRs are enriched, while group IV PCCRs are depleted in 75-nt windows immediately adjacent to splice sites. In all panels, boxplots (represented by the median, upper and lower quartiles, upper and lower fences; outliers are not shown) correspond to n = 40 randomizations; * and *** denote a statistically discernible difference at the 5% and 0.1% significance level, respectively (in panels B and C for a two-tailed Wilcoxon’s test with H0: enrichment = 1).

Fig. 3 Splicing. A Control procedures. In the random shift control, a PCCR is shifted within the gene. In the random gene control, a pseudo-PCCR is created in the same relative position of a different gene chosen at random. The number of PCCRs inside, outside, and crossing the reference set of intervals (e.g., introns) are counted. B PCCRs are enriched inside introns and depleted in outside and crossing configurations. C PCCRs looping out exons are depleted. D The cumulative distribution of the average exon inclusion rate (Ψ) in HepG2 cell line for exons looped out by PCCRs of the four energy groups vs. exons not looped out by PCCRs (Ctrl). KS denotes the two-sample Kolmogorov-Smirnov test. Sample sizes for energy groups I-IV and control are n = 73,366, 13,974, 1877, 374, and 161,947, respectively. E The distribution of distances from intronic PCCRs to intron ends (bin size 75 nts). Group I PCCRs are enriched, while group IV PCCRs are depleted in 75-nt windows immediately adjacent to splice sites. In all panels, boxplots (represented by the median, upper and lower quartiles, upper and lower fences; outliers are not shown) correspond to n = 40 randomizations; * and *** denote a statistically discernible difference at the 5% and 0.1% significance level, respectively (in panels B and C for a two-tailed Wilcoxon’s test with H0: enrichment = 1).
random gene control, and the enrichment and depletion remained significant (Fig. 3B, bottom). A similar comparison with the set of annotated exons revealed a substantial depletion of PCCRs that loop out exons, which also became stronger as PCCR stability increased (Fig. 3C). The average inclusion rate of exons that were looped out by PCCR was lower than that of exons that are not surrounded by PCCR, with the magnitude of the difference increasing for more stable structures (Fig. 3D). These results reconfirm that PCCRs generally tend to avoid placing exons in a loop, which promotes exon skipping.

The frequency of intronic PCCRs decays with increasing the distance to intron ends in all four energy groups partially reflecting the decrease of sequence conservation (Fig. 3E). However, weaker structures occur more frequently in 75-nt windows adjacent to splice sites, while stronger structures tend to occupy more distant positions. The ends of PCCRs tend to be closer to exon boundaries than would be expected by chance from random shifts (Fig. S8). Contrary to what was reported earlier for Drosophila melanogaster, there is no substantial depletion of CCR in polypyrinimidine tracts (PPTs). This indicates a large regulatory potential for splicing since a large fraction of CCR that overlaps PPT (43.2%) also blocks the acceptor splice site. In addition, there were on average 20% fewer overlaps of CCR with intronic branch points than would be expected from random shift control, that is, CCRs tend not to overlap intronic branch points.

To test whether PCCRs interfere with splicing signals, we identified intronic motifs with high similarity to donor and acceptor site consensus sequences (cryptic splice sites) and analyzed the expression of splice sites in a large compendium of RNA-sequencing (RNA-seq) samples from the Genotype Tissue Expression Project (GTEx)43. CCRs overlapping highly expressed (active) splice sites were depleted, while CCRs overlapping splice sites with low read support (inactive) were enriched (Fig. 4A). CCRs overlapping non-expressed cryptic splice sites were also enriched with the exception of highly stable structures, which are likely devoid of cryptic splice sites due to high GC content. We also found that the largest enrichment of CCRs overlapping candidate cryptic splice sites was among PCCR with small spread (MW test, p value = 0.004), in agreement with the previous findings that cryptic splice sites tend to be suppressed by local RNA secondary structure44,45.

RNA secondary structure has been suggested to be a defining feature that leads to backsplicing and formation of circular RNAs (circRNA)46. A comparison with the set of circRNAs from the tissue-specific circRNA database (TCSD)47 by random shift and random gene controls revealed a pattern opposite to that of linear introns, in which PCCRs were enriched outside circRNAs and depleted inside circRNAs (Fig. 4B). This supports the hypothesis that circRNAs originate from loop-out sequences that are formed by stable double-stranded RNA structures46.

**RNA editing.** A widespread form of post-transcriptional RNA modification is the enzymatic conversion of adenosine nucleosides to inosine, a process called A-to-I editing, which is mediated by the adenosine deaminase acting on RNA (ADAR) family of enzymes48,49. Since ADAR editing occurs in double-stranded RNA substrates50,51, we asked whether A-to-I editing sites are enriched among CCRs (Fig. 4C). We observed a strong enrichment of ADAR-edited sites that are documented in the RADAR database (2,576,459 sites) within CCR as compared to non-CCR parts of CIRs (odds ratio (OR) = 2.1 ± 0.2). While the OR was nearly the same for PCCR with energy from −15 to −30 kcal/mol, it dramatically increased for PCCR with the energy < −30 kcal/mol (2.1 ± 0.2 vs. 13.2 ± 5.0), reconfirming previous observations that ADAR targets are long double-stranded RNAs52. The OR was also significantly greater (1.7 ± 0.2 vs. 22.2 ± 13.1) for PCCR with higher evidence of compensatory mutations, but it did not depend significantly on the PCCR spread. These results were concordant with each other for the datasets of A-to-I editing sites from RADAR and REDIportal databases53,54 and can be regarded as an additional support for double-stranded structure of PCCRs.

**5′-end and 3′-end processing.** Recent reports indicate that RNA structure is important for the 3′-end processing of human mRNAs55, and that competing RNA base pairings could be involved in alternative splicing and polyadenylation in the 3′-variable region56. In this section, we characterize the relationship between PCCRs, 5′-end, and 3′-end mRNA processing using the data from transcript annotation databases56 and clusters of poly(A)-seq and cap analysis of gene expression (CAGE) tags57,58.

First, we estimated the number of transcripts that start or end within CCRs, including all incomplete and aberrant isoforms that are annotated in GENCODE (Fig. 4D). Both 5′- and 3′-ends were enriched inside CCRs, suggesting that double-stranded structures are associated with the suppression of aberrant transcripts. Next, we asked whether the annotated 5′ and 3′-ends of transcripts were enriched in the inner part of CCRs, that is, in the regions between paired CCRs. Indeed, both were significantly enriched, and the magnitude of the enrichment increased with increasing PCCR stability (Fig. 4E). The random gene control confirmed that the effect was not due to nonuniform distribution of PCCRs. To rule out the possibility that non-expressed isoforms contribute to the observed enrichment, we additionally examined the expressed CAGE tags and poly(A)-seq clusters and found that they were also significantly enriched within PCCR (Fig. S9). Since PCCRs are, in turn, enriched inside introns, this motivated us to analyze triple associations between RNA structure, splicing, and end processing.

Thus, we asked whether the annotated transcript ends, CAGE tags, and poly(A)-seq clusters occur more frequently in introns that contain PCCRs. However, introns with PCCRs tend to be also longer than introns without PCCRs, which may affect the above frequencies. Hence, we subdivided all annotated introns into two groups, introns with PCCR (IWP) and introns without PCCR (IWO), and selected two samples from IWP and IWO, 38,119 introns each, with matching intron lengths (Fig. S10). Of these, 12,782 (33.5%) IWP contained at least one annotated 5′-end, while only 9,575 (25.1%) IWO did so (OR = 1.50 ± 0.05). Similarly, 12,042 (31.6%) IWP contained at least one annotated 3′-end, compared to 8,978 (23.6%) for IWO (OR = 1.50 ± 0.05). The enrichment of both 5′ and 3′-ends in IWP raises an intriguing hypothesis that there could be an RNA structure-mediated coupling between splicing and end processing (see “Discussion”).

**Mutations.** Mutations generally lower the stability of RNA secondary structure, and some of them are under evolutionary selection owing to their effects on the thermodynamic stability of pre-mRNA59. In order to estimate the impact of human population polymorphisms on PCCRs, we analyzed single-nucleotide polymorphisms (SNPs) from the 1000 Genomes project60 and compared SNP density in CCR with that in the remaining parts of CIR. Germline SNPs were significantly underrepresented in CCR (0.0196 vs. 0.0207 SNPs per nt, one-tailed Poisson test, p value < 0.01). Next, for each SNP that occurs in a PCCR, we calculated the free energy change caused by the mutation and compared it to the free energy change that would have been observed if the same mutation occurred at a different position of the same CCR (Fig. S11A). It turned out that actual SNPs destabilized PCCRs less than it would be expected by chance (Wilcoxon’s test,
suggesting that SNPs generally tend to minimize their destabilizing impact on RNA structure.

Compensatory mutations may also occur in the human population, but at a substantially lower frequency. To estimate the frequency of compensatory population polymorphisms, we identified PCCRs that contain SNPs with an allele frequency of 1% and higher. Out of 64,074 bp in PCCRs that were affected by SNPs, only 12 showed sufficient support for compensatory mutations. After randomization, in which the pairs of complementary nucleotides were randomly switched, the respective average values were 64,132 and 0.06 (see “Methods,” Fig. S11B). The density of compensatory mutations normalized to the number of base pairs with mutations were 0.019% for the actual base pairs and (9.0 ± 7.3) × 10−5% for the randomized set. From this we conclude that, despite compensatory mutations within PCCR are quite rare in the human population, they are significantly enriched (one-tailed Poisson’s test, P < 0.01).

**RBP binding sites.** Multiple lines of evidence indicate that binding of RNA-binding proteins (RBPs), which is crucial for co- and post-transcriptional RNA processing, depends on RNA structural context. To assess the association between long-range RNA structure represented by PCCRs and RBP binding, we computed eCLIP peak frequencies in the vicinity of CCRs and compared them to the background eCLIP peak frequencies in CIRs surrounding CCRs. Among factors that showed a substantial enrichment, there were RBPs that are known to exert their function in conjunction with RNA structure such as RBFOX2 and factors that favor increased structure over their motifs such as SRSF9 and SFPQ (Fig. 5A). For RBPs with single-stranded RNA-binding activity such as ILF3 and hnRNPA1, we observed a significant depletion of binding sites within CCRs (Fig. S12).

One of the features of the eCLIP protocol is that an RBP can crosslink with either RNA strand that is adjacent to the

**Fig. 4 Splicing, RNA editing, and end processing.** A CCRs are depleted around actively expressed splice sites and enriched around inactive and cryptic splice sites. B PCCRs are enriched outside back-spliced introns (circular RNAs from TCSD, ref. 47) and depleted in inside and crossing configurations. C CCRs are enriched with A-to-I RNA-editing sites (RADAR REDiportal53,54); OR denotes the odds ratio (see “Methods”); error bars represent the 95% confidence intervals. D CCRs are enriched with 5’ and 3’ ends of transcripts annotated in GENCODE database (including all aberrant and incomplete transcripts). That is, transcript ends frequently occur in double-stranded parts of PCCRs. E PCCRs are also strongly enriched with 5’ and 3’ ends of transcripts, that is, the annotated transcript ends frequently occur in the loop between double-stranded parts of PCCRs. In all panels, boxplots (represented by the median, upper and lower quartiles, upper and lower fences; outliers are not shown) correspond to n = 40 randomizations; *, **, and *** denote a statistically discernible difference at the 5%, 1%, and 0.1% significance level, respectively, for a two-tailed Wilcoxon’s test with $H_0: enrichment = 1$. 

$p$ value < 0.001, suggesting that SNPs generally tend to minimize their destabilizing impact on RNA structure.
double-stranded region. Hence, we expect a higher chance of observing an eCLIP peak near the CCR given that the other CCR in the pair contains a nearby peak, a situation that will be referred to as forked eCLIP peak. To estimate the magnitude of this association, we computed the respective OR and found that the vast majority of RBPs (64 out of 74, \( p \) value < 10\(^{-12} \)) indeed have a substantially higher likelihood of binding close to a CCR given that they bind the other CCR in a pair (Fig. 5B). This can be regarded as independent evidence for double-stranded structure of PCCRs. Interestingly, the largest OR was observed for TAF15, a TBP-associated factor 15, which is not a double-stranded RNA (dsRNA)-binding protein itself, but interacts with FUS, which is capable of binding dsRNA\(^70\). Similarly, ILF3, which showed a depleted RNA binding within CCRs, nevertheless is positively associated with forked eCLIP peaks, suggesting its binding at single-stranded regions adjacent to PCCRs. This indicates, on the one hand, that RBP binding is inseparable from the surrounding RNA structure and, on the other hand, that eCLIP peaks may not correctly reflect the actual binding positions of RBPs since they are affected by intramolecular base pairings and interactions with other players.

**RNA Pol II elongation speed.** The kinetic model of co-transcriptional splicing suggests that RNA Pol II elongation slowdown expands the “window of opportunity” for the recognition of weak splice sites, thereby increasing the rate of inclusion of upstream exons\(^71,72\). Besides this direct impact on splice site recognition, slow RNA Pol II elongation may also affect the way the transcript folds, which is another important determinant of
how the transcript will be processed by the splicing machinery. To investigate the role of long-range RNA structure in co-
transcriptional splicing, we performed RNA-seq experiments, in which we used α-amanitin to slow down the RNA Pol II elongation speed, and additionally analyzed publicly available data on the impact of RNA Pol II elongation speed on splicing.

The expected consequence of the RNA Pol II slowdown is that the inclusion rate of exons that follow short introns will increase, and the inclusion rate of exons that follow long introns will decrease. Indeed, this trend was observed both when RNA Pol II elongation speed was decreased by α-amanitin and in the slow RNA Pol II mutant R749H (Fig. 5C). To check whether RNA Pol II slowdown differently affects introns with and without PCCRs, we matched each exon that follows an intron containing a PCCR with a randomly chosen exon that follows an intron of the same length, but without PCCRs. The difference in inclusion rates of these matched exons showed that exons that follow an intron with a PCCR tend to be more included than exons following an intron without PCCRs at both concentrations of the inhibitor and in R749H RNA Pol II mutant (Fig. 5D). This can be considered as evidence for RNA Pol II slowdown to affect exon inclusion through pre-mRNA folding, in addition to modulation of splice site recognition. Namely, slower RNA Pol II elongation speed may not only facilitate the processing of upstream splice sites by the spliceosome but also allow sufficient time for the intrinsic RNA structure to fold, thus promoting exon inclusion. A particular example of such a kinetic mechanism linked to RNA structure was reported for the Ate1 gene, in which a long-range base pairing dynamically regulates the ratio of mutually exclusive exons.

Case studies. In this section, we focus on the association of long-range base pairings with RBP binding in the context of two particular splicing-related mechanisms, RNA bridges, and exon loop-outs.

To identify potential RNA bridges, that is, long-range RNA structures that bring an RBP binding site closer to the regulated exon, we searched for candidate binding sites of RBPs profiled by eCLIP that were located within 50 nts from a CCR, on the one hand, and exons located within 50 nts from its mate CCR, on the other hand. To detect regulation, we additionally required that exon inclusion rate significantly respond to shRNA knockdown (shRNA-KD) of the same factor using the data on RBP KDs produced by the ENCODE Consortium (see “Methods”). This procedure yielded a set of 296 candidate RNA bridges (Supplementary Data File 3), including the RNA bridge that controls the inclusion of exon 12 of ENAH gene (Fig. 6A). A PCCR with the hybridization energy $-19.8 \text{kcal/mol}$ coincides with the core part of the RNA stem that was reported earlier. We confirm that it is surrounded by forked eCLIP peaks of RBFOX2, which reflects cross-linking next to the double-stranded region, and that the inclusion of exon 12 drops by 43% ($\Delta$Ψ = -0.43) upon RBFOX2 KD. However, we also find a nested PCCR with the hybridization energy $-20.4 \text{kcal/mol}$, which suggests that the RNA bridge extends much further than it was reported originally. As a novel example, we describe a candidate RNA bridge in the 3’ end of RALGAPA1 gene, which encodes the major subunit of the RAL-GTPase-activating protein. In this gene, a group of nested PCCRs approximates binding sites of RBFOX2 and QKI to the penultimate exon (Fig. 6B). The KD of each of these factors promotes exon skipping, which indicates that exon inclusion depends on the binding of RBFOX2 and QKI through a RNA bridge.

In a similar way, we identified candidate base pairings that loop out exons by searching for PCCRs that surround an exon and contain an RBP binding site within one of the CCRs. In addition, we required that the exon significantly respond to RBP KD. This procedure yielded a set of 1135 candidate exon loop-outs (Supplementary Data File 4). Among them, there were two nested RNA structures looping out exon 24 of GPR126, the human G protein-coupled receptor 126, in which one of the CCRs overlaps a RBFOX2 binding site, and the exon responds to RBFOX2 KD (Fig. 6C). Another example is the alternative 3’-end exon in FGFR1OP2, fibroblast growth factor receptor 1 oncogene partner 2, which is suppressed by QKI KD and, at the same time, is looped out by a PCCR that overlaps a QKI binding site (Fig. 6D).

Data visualization and availability. The tables listing PCCRs for GRCh37 and GRCh38 human genome assemblies are available in BED format as Supplementary Data Files 1 and 2, respectively. These predictions are visualized through a track hub for the UCSC Genome Browser. In order to connect the track hub, the following link https://raw.githubusercontent.com/kalmSveta/PCCR/master/hub.txt can be copied and pasted into the form https://genome.ucsc.edu/cgi-bin/hgHubConnect#unlistedHubs. The PCCR tracks are grouped by the energy groups, spread, and $E$ value. Along with PCCRs, we additionally report the response of exons to RNA Pol II elongation slowdown, iSHAPE reactivity scores, and RIC-seq predictions. The tables listing the predicted RNA bridges and looping-out PCCRs are available as Supplementary Data Files 3 and 4, respectively. They are visualized through https://raw.githubusercontent.com/kalmSveta/RNA-bridges/master/hub.txt, along with eCLIP data and exon responses to shRNA KDs. Supplementary Data Files are available online through ZENODO repository https://zenodo.org/record/4603132 (also see https://doi.org/10.5281/zenodo.4603132) and via http://arkuda.skoltech.ru/~dp/shared/PrePH/.

Discussion

It has been increasingly acknowledged that RNA structure plays a critical role in the regulation of eukaryotic gene expression at all steps from transcription to translation, but little attention has been paid to long-range RNA structure. From the thermodynamic standpoint, long-range base pairings contribute to the enthalpy of RNA folding as much as local base pairings do, and the corresponding energy figures exceed by an order of magnitude the typical folding energies of globular protein domains. However, since RNA structure affects, and is itself strongly affected by RBP binding, a reliable prediction of long-range RNA structure in full-length eukaryotic transcripts does not seem feasible at the current state of the art. Instead of the detailed structure, here we consider as a proxy for RNA structure the core of highly stable and evolutionarily conserved double-stranded regions, different combinations of which may represent one or several physiologically relevant folds.

The existence of associations between long-range RNA structure and splicing has been noted in the previous studies, including our earlier reports. The trends that were proposed for smaller sets also hold for the extended catalog of PCCRs presented here, namely, the preference of PCCRs to be positioned within introns proximally to splice sites, lower inclusion rate of looped out exons, circumscription of circRNAs, avoidance of intronic branch points, and generally obstructive effect on splice sites that are implicated in double-stranded structure. We additionally observed a remarkable overlap of PCCRs with A-to-I RNA-editing sites and multiple associations with forked eCLIP peaks, which reveal traces of multimolecular complexes with patterns that are specific to double-stranded regions. These findings reconfirm the well-known mechanism of ADAR-mediated pathway and show the importance of RNA structure for the assembly of
RNA–protein complexes, with a preference for some RBPs and avoidance for the others. At the same time, they may also be regarded as independent support for double-stranded structure of PCCRs in addition to the evidence from experimental RNA structure profiling and compensatory substitutions.

The components of RNA-processing machinery operate in a strict coordination not only in space but also in time. The kinetic profile of RNA Pol II elongation has a significant impact on alternative splicing. Slow RNA Pol II elongation generally opens a window of opportunity for weak splice sites to be recognized, leading to higher inclusion of alternative exons, although in some cases the effect can be quite opposite. Slow RNA Pol II elongation may also influence poly(A) site choice by enhancing the recognition of suboptimal polyadenylation signals (PASs).

Consistent with this, we observe an increased inclusion of exons that are preceeded by shorter introns. We also observe an additional component to this general trend, one in which structured and unstructured RNAs respond differently to RNA Pol II slowdown. This observation indicates that long-range RNA structure could coordinate the interaction between spatial and temporal components of splicing regulation. The example of long-range RNA structure in the Ate1 gene demonstrates that mechanisms similar to bacterial attenuation may also take place in eukaryotic cells.

RNA structure is implicated in the recognition of PASs by cleavage and polyadenylation specificity factor (CPSF)

**Fig. 6 Case studies.** A. An RNA bridge in ENAH gene brings a distant RBFOX2 binding site into proximity of the regulated cassette exon. The exon inclusion rate substantially decreases under RBFOX2 depletion ($\Delta \Psi = -0.43$). B. The predicted RNA bridge in RALGAPA1 brings distant binding sites of RBFOX2 and QKI to the regulated exon. The exon significantly responds to the depletion of these two factors ($\Delta \Psi = -0.28$ and $\Delta \Psi = -0.75$, respectively). C. A cassette exon in GPR126 is looped out by a PCCR overlapping an eCLIP peak of RBFOX2 and significantly responds to RBFOX2 depletion ($\Delta \Psi = -0.56$). D. An alternative terminal exon in FGFR1OP2 is looped out by a PCCR overlapping an eCLIP peak of QKI and significantly responds to QKI depletion ($\Delta \Psi = -0.48$). In all panels, exon inclusion rate changes are statistically significant ($q$ value < 0.01).
facilitates the 3′-end processing by juxtaposing PAS and cleavage sites that are otherwise too far apart. Functional RNA structures in 5′-untranslated regions are also implicated in the regulation of translation. While these reports mostly concern local RNA structure, an intriguing finding of this work is the link between long-range RNA structure and pre-mRNA 3′-end processing, which is manifested by the enrichment of poly(A)-seq clusters in the inner part of PCCRs. It indicates that mechanisms other than sequestration or spatial convergence of PAS and cleavage sites may be involved. In fact, human genes contain thousands of dormant intronic PASs that are suppressed, at least in part, by U1 small nuclear ribonucleoproteins in a process called telescripting. While the exact mechanism of this suppression is not known, many intronic PASs were found to be associated with CstF64, a ubiquitous pre-mRNA 3′-processing factor, suggesting that cleavage and polyadenylation machinery may actually operate in all introns constitutively. Could it be that RNA structure helps to suppress premature intronic polyadenylation?

Figure 7 illustrates a hypothetical mechanism of suppression of intronic polyadenylation by co-transcriptional splicing, which explains the enrichment of poly(A)-seq clusters in the inner parts of PCCRs. Indeed, the cleavage and polyadenylation of a structured pre-mRNA could be rescued by co-transcriptional excision of the intron, while RNA structure stabilizes the molecule through intramolecular base pairings despite the disruption of the backbone (Fig. 7A). However, such a rescue would not happen in unstructured RNAs when splicing has a delay relative to cleavage and polyadenylation (Fig. 7B). This scenario is further supported by a conspicuous association between transcript 5′ and 3′ ends in exhaustive transcriptome annotations, a typical example of which is an intron that contains a 3′ end of protein-coding transcript and a 5′ end of another, usually noncoding transcript (Fig. S7). It is 2.86 ± 0.10 times more likely to see a 5′ end in an intron that contains a 3′ end, and hence the enrichment of poly(A)-seq clusters within PCCRs also implies the enrichment of 5′ ends and CAGE clusters. The described mechanism could be responsible for the generation of transcripts with alternative 3′ ends, for example, for the RNA structure-mediated switch between splicing and polyadenylation in the Nmnat gene in D. melanogaster.

RNA structure probing by isSHAPE and the assessment of long-range RNA–RNA interactions by photo-inducible RNA cross-linking are the most current techniques for global analysis of RNA structure in vivo. However, these data reflect gene expression patterns that are specific to cell lines, in which they were generated, and have strong undercoverage bias in intronic regions, which are spliced out and degraded. The reduction of the intronic signal is also a common problem for RNA cross-linking and immunoprecipitation experiments. In addition, it was meaningful to compare PCCRs only to intramolecular RNA contacts that belong to CIRs and do not exceed the distance limit of 10,000 nts. Consequently, the validation with respect to these assays was possible only for a small number of PCCRs, on which the comparison, however, showed a concordant result (Table 2). On the other hand, the fact that 2961 out of 916,360 PCCRs were supported by RIC-seq is highly significant compared to the expected intersection of 381 structures for two interval sets of the same size obtained by random shifts.

The major problem of the current method is the high number of false-positive predictions. On the one hand, the procedure for the estimation of FDR is based on the assumption that pre-mRNAs of different genes do not interact with each other, and that regulatory sequences in different genes evolve independently. However, psoralen cross-linking and proximity RNA ligation assays have demonstrated that this assumption may not be completely true because RNA–RNA interactions in trans are highly abundant. Therefore, the re-wiring control overestimates FDR, as it did in previous works. On the other hand, the amount of random complementarity in CIRs is, indeed, quite large. For instance, two intronic binding sites of a transcription factor that occur on opposite DNA strands will be detected as a PCCR, and they may even be supported by spurious compensatory substitutions that result not from selective constraints on RNA structure, but from evolving specificity of the binding site. An example of this is the RP11-439A17.4 lncRNA, a part of which is complementary to conserved sequences in 22 mammalian histone genes, but the complementary elements are, in fact, the binding sites of MEF-2A, a myocyte-specific transcription factor. Evolution maintains them conserved and technically complementary for reasons other than base pairing, which makes this situation in principle indistinguishable from evolutionary selection acting on true RNA structures. To reduce FDR, a significant improvement could be achieved by combining the methodology presented here with the emerging experimental methodological advances.
strategies for profiling of RNA–RNA contacts such as RIC-seq. This appears to be the most promising direction for future research.

In sum, eukaryotic pre-mRNAs are structured macromolecules with base pairings that span long distances, and RNA secondary structure plays a critical role in their processing. Here, we presented the most complete up-to-date catalog of CCRs in human protein-coding genes and provide their extensive characterization. In spite of the high false-positive rate, the predicted double-stranded RNA structures show significant associations with virtually all steps of pre-mRNA processing. We offer this catalog for common use as a reference set and provide its convenient visualization through a UCSC Genome Browser track hub.

Methods

Genomes and transcript annotations. February 2009 (hg19, GRCh37) and December 2013 (hg38, GRCh38) assemblies of the human genome were downloaded from Genome Reference Consortium. These assemblies were used with GENCODE transcript annotations v19 and v33, respectively. Only genes labeled “protein coding” were analyzed. Transcript annotations were parsed by custom scripts to extract the coordinates of exons and introns. The results for GRCh37 assembly are reported throughout the paper; however, Genome Browser track hubs (see below) contain tracks for both GRCh37 and GRCh38 assemblies.

Filteration of intronic regions. The intronic regions were defined as the longest continuous segments within genes that do not overlap any annotated exons (including exons of other genes). The intronic regions were extended by 10 nts into the flanking exons to enable the identification of CCRs that overlap splice sites such as regions R1–R5 in the human Ate1 gene. These regions were intersected with the set of conserved RNA elements (phastConsElements track for the alignment of 99 vertebrates genomes to the human genome99) using bedtools.100 We additionally excluded genomic regions that overlap intervals from the UCSC Genome Browser rRNA track101, sno/miRNA track102, TFS Conserved track, and the Genome Browser track containing helix hybridization energies for all pairs of nucleotides, for which the icSHAPE reactivity score was available. The background nucleotides per amino acids table containing helix hybridization energies for all pairs of amino acids was also used in the analysis. GO enrichment analysis was performed by controlling for the gene length since genes with PCCRs tend to be longer than genes without PCCRs. We randomly matched each gene with PCCRs to a gene without PCCR of approximately the same length. The enrichment of GO terms between these two gene sets was calculated with clusterProfiler R package.

PrePH. The first reference to long-range RNA structure appeared in the literature under the term “panhandle structure,” which was coined by virologists in the 1980s to refer to a complementary base pairing between the 5’ end and 3’ end of the RNA genome of several segmented negative-stranded viruses.39 The PrePH utility uses a k-mer based technique, which is similar to previously published IRBS method, to identify all pairs of nearly perfect complementary regions in a given pair of sequences. At the preparatory step, PrePH pre-computes complementary regions passing the energy threshold (by default $k=5$) that are either Watson–Crick complementary or contain a few GT base pairs (by default at most two) using energy tables from Vienna RNA package.20 The dynamic programming matrix is computed by local Smith–Waterman algorithm using a limited set of structural rules: initiating a k-nt-long helix, extending a helix by a stacking base pair, and adding to a helix a short internal loop or bulge with up to m nucleotides in each strand (default $m=2$), followed by another helix. To speed up back-tracking, PrePH uses auxiliary matrices to store intermediate structures, and reports nonintersecting pairs of complementary regions passing the energy threshold (by default $-15$ kcal/mol). Here, two pairs of complementary regions, $x_1$ complementary to $y_1$ and $x_2$ complementary to $y_2$, are referred to as intersecting if $x_1$ has common nucleotides with $y_2$, and $x_2$ has common nucleotides with $y_1$. The coordinates of intramolecular base-paired regions not intersecting are used in the analysis. The reducing scoring scheme, optimized back-tracking, and indexing of the initial sequences by k-mers result in a great improvement of computation speed. The detailed description of PrePH is exempt to Supplemental Methods. PrePH software is available at github (https://github.com/kalmsvet/PrefPH) (codes are available at: https://doi.org/10.5281/zenodo.4601044).

Benchmarks. We compared the accuracy and runtime of PrePH to those of other programs such as IntaRNA,2, RfamSearch,2, RNAplex,2, DuplexFold,124, and bifold.24 PrePH was run with the following parameters: $k$-mer length is 5 nts, maximal distance between complementary regions is 10,000 nts, the minimal length of the aligned regions is 10 nts, the energy threshold is $-15$ kcal/mol, and the maximal number of Wobble pairs in a $k$-mer is 2. The parameters for other programs are listed below.

To benchmark the time efficiency, we use a set of 1000 pairs of randomly chosen conserved intronic sequences from the human genome. The sequences were 50 nts long and contained a perfect base pair complementarity.

The programs were run with the energy threshold set to $-15$ kcal/mol. IntaRNA2.0 outOverlap parameter was set to B, which allowed overlap for interacting subsequences for both target and query; $n$ parameter was set to 100 to limit the maximal number of suboptimal structures; $q$Acc and $e$Acc were set to N to omit the computation of accessibility ($n$ denotes the cardinality of a set). The number of base pairs that were common between PrePH and each of the other programs as a fraction of the number of base pairs predicted by PrePH alone was used as a measure of specificity (Table S2B). PrePH showed specificity $>80\%$ with respect to all other programs except bifold; however, the latter was not in agreement with all other programs.

We conclude that PrePH allows for computationally efficient detection of PCCRs without significant loss of accuracy compared to other methods. The computation time of PrePH on the complete dataset of CIRs was 4 h (15 threads, 1200 MHz CPUs each).

Relative position within the gene. The relative position of a genomic interval [x, y) in the containing gene [a, b], where x, y, a, and b are genomic coordinates on the positive strand, was calculated as $\lfloor (y - x) / (b - a) \rfloor$. The coordinates for the negative strand the value of $1 - p$ was used instead.

GO enrichment analysis. GO enrichment analysis was performed by controlling for the gene length since genes with PCCRs tend to be longer than genes without PCCRs. We randomly matched each gene with PCCRs to a gene without PCCR of approximately the same length. The enrichment of GO terms between these two gene sets was calculated with clusterProfiler R package.

Experimental RNA structure data. The icSHAPE reactivity scores were mapped from GRCH38 to GRCh37 human genome assembly by LiftOver. The reactivity score of a CCR was calculated as the average reactivity of its base-paired nucleotides, for which the icSHAPE reactivity score was available. The background reactivity was calculated as the average reactivity of the same number of nucleotides chosen at random outside the CCR, but in the same CIR. Wilcoxon’s signed-rank test was applied to matched samples of reactivity score differences to test for departures from zero.

The coordinates of base-paired regions from PARIS experiments22 (15,036 pairs) were mapped from GRCh38 to GRCh37 by LiftOver. The coordinates of base-paired regions from LIGR-seq data (551,926 pairs) were used in the GRCh37 human genome assembly.23 The coordinates of intramolecular base-paired regions from RIC-seq data4 (501,144 pairs) were kindly provided by Prof. Xue by request (Supplementary Data File 5). In all three datasets, we selected the interacting pairs that were located intramolecularly within CIR of protein-coding genes from 1 to 10,000 nts apart from each other. This resulted in 967 such pairs for PARIS, 586 for LIGR-seq, and 1804 for RIC-seq. In order to evaluate the precision and recall, we selected CIR with at least one nucleotide overlapping the experimentally validated structures and confined our analysis to PCCRs located in these regions. A CCR was classified as a true positive if it had at least one common nucleotide with an experimentally validated structure. A CPCR was classified as a true positive if both its CCRs intersected by at least one nucleotide with an experimentally validated such pair.

Cell culture, treatments, and RNA purification. A549 cell line (kindly gifted by Dr. Ilya Terenin, Moscow State University) was maintained in Dulbecco’s modified Eagle’s medium/Nutrient Mixture F-12 medium containing 10% fetal bovine serum (Thermo Fisher Scientific), 100 U/ml penicillin, and 0.05 mg/ml streptomycin (both from Thermo Fisher Scientific) at 37°C in 5% CO₂. Cell line authentication was confirmed using short tandem repeat analysis. The cell line was tested for the absence
of mycoplasma using MycoReport kit (EuroGene). For α-amanitin (Sigma) treatments, 1 and 2 μg/mL of α-amanitin was added to cells at 30–70% confluency. After 24 h of treatment, cells were harvested, total RNA was isolated using PureLink RNA Mini Kit (Thermo Fisher Scientific). Poly(A)^+ mRNA was purified using Dynabeads Oligo(DT) 25 (Thermo Fisher Scientific) following the manufacturer’s instructions.

**Library preparation and RNA-seq.** Illumina cDNA libraries were constructed using NEBNext Ultra II Directional RNA Library Prep Kit for Illumina (New England Biolabs) following the manufacturer’s protocol with the only modification: the change of fragmentation time from 15 to 10 min. Complementary DNA libraries were sequenced using the NextSeq500 (Illumina, San Diego, CA, USA) instrument; 33–41 million raw reads were obtained for each sample with a 75 bp read length. The results of RNA-seq have been deposited at Gene Expression Omnibus under the accession number GSE153303.

**Splicing quantification.** RNA-seq data of poly(A)^+ RNA for the HepG2 cell line (accession numbers ENCF676016 and ENCF701472) were downloaded in BAM format from the ENCODE Consortium website. Short-hairpin shRNA-KD of 250 RBPs followed by RNA-seq data were downloaded in BAM format from ENCODE data repository. The reads from wild-type Amnr and Rphi CA/R749H mutant HEK293 cells treated with α-amanitin for 42 h were downloaded from the Gene Expression Omnibus (GSE63375). RNA-seq data of poly(A)^+ RNA data from the A549 cell line treated with α-amanitin were obtained as explained below and mapped to the GRCh37 human genome assembly using STAR aligner v2.3.1z with the default settings. The coordinates of circRNA molecules were obtained as explained below and mapped to the GRCh37 human genome assembly using STAR aligner v2.3.1z with the default settings. The coordinates of circRNAs expressed in liver tissue and their associated SRPTM metrics (the number of circular reads per number of mapped reads per read length) were obtained from the TCDS database. The genomic coordinates of adenine branch point nucleotides were selected from the validated set of branch points expressed in K562 cells.

RNA-seq experiments were processed by IJPSA pipeline to obtain split read counts supporting splice junctions. Split read counts were filtered by the entropy content of the offset distribution, annotation status, and canonical GT/AG content of the offset distribution, annotation status, and canonical GT/AG content of the offset distribution. The maximum number of reads supporting exon inclusion and exclusion was computed according to the equation

\[
\Psi = \frac{inc}{inc + 2 \times exc}
\]

where inc is the number of reads supporting exon inclusion and exc is the number of reads supporting exon exclusion. \(\Psi\) values with the denominator <10 were considered unreliable and discarded. Differential exon inclusion between a pair of conditions (shRNA-KD vs. non-specific control and α-amanitin vs. untreated control) was assessed as described previously.

Cryptic and actively expressed splices sites in the human transcriptome were identified using genomic alignments of RNA-seq samples from the GTEx Consortium. Splice sites with the canonical GT/AG dinucleotides at splice sites with the default settings, and pooled between bioreplicates. The exon inclusion rate (Psi, PSI, or Percent-Spliced-In) was calculated according to the equation

\[
\Psi = \frac{inc}{inc + 2 \times exc}
\]

where inc is the number of reads supporting exon inclusion and exc is the number of reads supporting exon exclusion. \(\Psi\) values with the denominator <10 were considered unreliable and discarded. Differential exon inclusion between a pair of conditions (shRNA-KD vs. non-specific control and α-amanitin vs. untreated control) was assessed as described previously.

Splice sites within the same conserved regions were identified as regions with high homology (sequence similarity >90% over the same length) and with the same splicing pattern in at least two species.

**5’ and 3’ UTRs.** The 5’ UTRs of human genes were obtained from the UCSC Genome Browser database (http://hgdownload.cse.ucsc.edu/hg19/). The 3’ UTRs were derived from the Ensembl database (http://www.ensembl.org/). The 5’ and 3’ UTRs were aligned using the Muscle alignment tool.

**eCLIP.** eCLIP peaks for 74 RBPs assayed in HepG2 human cell line were downloaded from the ENCODE data repository in bed format (Table S3). The peaks were filtered by the condition that the L and R peaks were merged through an algorithm that took into account the position of the peaks and the size of the peak. The eCLIP peaks were calculated for each RBP the number of CCRs that intersected with its eCLIP peaks by at least 50% of the CCR length. This number was compared to the respective number of intersections obtained using a random shift control. To quantify the association of RBP binding with both CCRs in a PCCR, we constructed a contingency table for the number of PCCRs that had/did not have eCLIP peaks in left/right CCR for each RBP, and computed the respective OR. The 95% confidence interval for the OR was calculated by Fisher’s test.

**Population polymorphisms.** To evaluate the enrichment of polymorphic changes in human and mouse, we used genotyping data from mouse strains and human populations.

**Sequence conservation and complementary substitutions.** To assess the degree of evolutionary conservation of a CCR, we computed the difference between the average PhastCons conservation score of all its nucleotides and the average PhastCons conservation score of the same number of nucleotides in its flanking regions within the same phastConsElements interval.

To assess the number of complementary substitutions in PCCRs and their statistical significance, we used the program MAVS to calculate the number of SNVs that occur in >1% of donors in the 1000 Genome Project and intersected their list with the list of base pairs in PCCRs. Among them, we estimated the number of base pairs, in which a compensatory mutation occurred in >1% of donors. To estimate the expected number of base pairs with compensatory mutations, we first subdivided base pairs into groups composed of the same base pair types (AT, TA, CG, GC, TG, GT) located on the same chromosome with the same orientation. The number of SNP donors. Then, we randomly interchanged (‘rewired’) base pairs within each group, for example, A1T1 and A2T1, and applied the same procedure again, that is, estimated the number of base pairs, in which compensatory mutations defined by SNVs occurred in >1% of donors (Fig. S6A). This randomization procedure was repeated 100 times.

**Statistical analysis.** The data were analyzed and visualized using R statistics software version 3.4.1 and ggplot2 package. Nonparametric tests were performed by built-in R functions using normal approximation with continuity correction. MW denotes Mann–Whitney sum of ranks test. Boxplots in all figures are represented by the median, upper and lower quartiles, and upper and lower fences; outliers are not shown. Error bars in all figures and the numbers after the ± sign represent 95% confidence intervals. Two-sided p values are reported throughout the manuscript unless the contrary is specified. The levels of significance 5%, 1%, and 0.1% in all figures are denoted by *, **, and ***, respectively.

**Data availability.** The raw-data sequences generated in this study are available through GEO repository under the accession code GSE153303.

Acknowledgements

RNA-sequencing was funded by Skolkovo Institute of Science and Technology. We thank Skoltech Genomics Core facility staff (Margarita Ezhova, Maria Logacheva) for library preparation and sequencing, and the Cobrain computer cluster for access to computational facilities. We also thank Prof. Yuanchao Xue and Prof. Changchang Cao for providing the list of clusters of chimeric reads for intramolecular interactions. S.K., S.D., and D.P. were supported by Russian Foundation for Basic Research Grant 18-29-13020-MK and by Skolkovo Institute of Science Technology Research Grant RF-0000000653. M.K. and D.S. were supported by Russian Foundation for Basic Research Grant 18-29-13020-MK.

Author contributions

D.P. and S.K. designed and carried out the analysis. M.K. and D.S. performed the experiments. S.D. and A.M. analyzed the evolutionary part. S.K., M.K., S.D., A.M., D.S., R.G., and D.P. analyzed the data and discussed the results. D.P. and S.K. wrote the paper.

Competing interests
