Subjective inner experiences, such as mind-wandering, represent the fundamentals of human cognition. Although the precise function of mind-wandering is still debated, it is increasingly acknowledged to have influence across cognition on processes such as future planning, creative thinking, and problem-solving and even on depressive rumination and other mental health disorders. Recently, there has been important progress in characterizing mind-wandering and identifying the associated neural networks. Two prominent features of mind-wandering are mental time travel and visuospatial imagery, which are often linked with the hippocampus. People with selective bilateral hippocampal damage cannot vividly recall events from their past, envision their future, or imagine fictitious scenes. This raises the question of whether the hippocampus plays a causal role in mind-wandering and, if so, in what way. Leveraging a unique opportunity to shadow people (all males) with bilateral hippocampal damage for several days, we examined, for the first time, what they thought about spontaneously, without direct task demands. We found that they engaged in as much mind-wandering as control participants. However, whereas controls thought about the past, present, and future, imagining vivid visual scenes, hippocampal damage resulted in thoughts primarily about the present comprising verbally mediated semantic knowledge. These findings expose the hippocampus as a key pillar in the neural architecture of mind-wandering and also reveal its impact beyond episodic memory, placing it at the heart of our mental life.

Key words: amnesia; episodic; hippocampus; mental time travel; mind-wandering; scenes

Introduction

Even when in the same place and involved in the same activity, at any given moment people can experience the world in different ways. Recently, there have been advances in delineating the various forms of spontaneous inner experiences and their neural correlates (Andrews-Hanna et al., 2014a; Christoff et al., 2016). Self-generated thinking typically refers to the ability to mentally decouple from current perceptual surroundings and generate independent internal thoughts (Smallwood and Schooler, 2015). These thoughts can either be task related, such as actively thinking about how this manuscript should be structured, or task unrelated, where there is a spontaneous inner focus, such as suddenly remembering what a nice time I had yesterday with my friends (Seli et al., 2016). These latter thoughts are the focus of the current study and have been variously described as task-unrelated, self-generated thoughts; daydreaming; or mind-wandering (Smallwood and Schooler, 2015).
It has been shown that humans tend to mind-wander ~30–50% of waking time, regardless of the current activity (Kane et al., 2007; Killingsworth and Gilbert, 2010). Nevertheless, mind-wandering frequency is particularly pronounced during restful periods and low-demanding tasks (Smallwood and Schooler, 2015). The latter is often exploited by experimentalists examining mind-wandering. Although the precise function of mind-wandering is still debated, it is increasingly acknowledged to have influence across cognition on processes such as future planning, creative thinking, and problem-solving (Baird et al., 2011, 2012) and even on depressive rumination and other mental health disorders (Ehlers et al., 2004; Andrews-Hanna et al., 2014a). Furthermore, the content of mind-wandering seems wide-ranging, including episodic memory recall (which involves a sense of re-experiencing and is specific in time and place), future planning, mentalizing, and simulation of hypothetical scenarios, and involves a variety of emotions and different sensory modalities (Andrews-Hanna et al., 2013; Smallwood et al., 2016). Interestingly, two of the most prominent features of mind-wandering are mentally traveling forward and backward in time and visual imagery, which are functions usually associated with the hippocampus (Tulving, 1985, 2002; Hassabis et al., 2007).

The default mode network (DMN), within which the hippocampus is a node, has been associated with self-generated thoughts such as mind-wandering (Buckner et al., 2008; Andrews-Hanna et al., 2014b). Of particular relevance here, stronger hippocampal connectivity with other regions of the DMN was observed in individuals who experienced more episodic details and greater flexibility in mental time travel during mind-wandering episodes (Smallwood et al., 2016; Karapanagiotidis et al., 2016). Unfortunately, causal evidence for hippocampal involvement in mind-wandering is lacking (Fox et al., 2016). Behavioral studies of patients with lesions are crucial because they permit examination of the causal effects of regional brain damage on the networks established by neuroimaging work. People with hippocampal damage cannot vividly recall events from their past (Lah and Miller, 2008), envision their future (Kurczek et al., 2015), or imagine fictitious scenes (Hassabis et al., 2007). Therefore, whether they experience mind-wandering and if they do what form does it take are important and timely questions that we addressed by examining mind-wandering in patients with selective bilateral hippocampal damage.

Previous studies have examined the effects of hippocampal damage during demanding tasks, such as autobiographical memory retrieval (Lah and Miller, 2008), designed to challenge the patients’ cognitive abilities. In contrast, to establish what patients with hippocampal damage think about spontaneously when there is no concurrent task, our focus was on what they do in their mentally “free” time. We initially asked whether or not patients with hippocampal damage were able to mentally decouple from the current perceptual input. If yes, we then had a series of additional questions. First, would they engage in mental time travel? Second, what form would their mind-wandering take: spontaneous episodic, detailed thoughts or semantic, abstract thoughts? Finally, we asked whether they experienced spontaneous visual imagery similar to that typically reported by control participants during mind-wandering (Andrews-Hanna et al., 2013).

**Materials and Methods**

**Participants**

Six patients [all right-handed males; mean age, 57.0 years (SD, 16.9); age range, 27–70] with selective bilateral hippocampal lesions and selective episodic memory impairment took part in the study (see Tables 1 and 2 for demographic information and neuropsychological profiles). Of note, these patients were the same high-functioning individuals that took part in our previous studies (McCormick et al., 2016, 2017a). Hippocampal damage (see example in Fig. 1a) resulted in all cases from voltage-gated potassium channel complex antibody-mediated limbic encephalitis. Two of the patients had bilateral signal hyperintensities in the hippocampi on presentation, but hippocampal atrophy was observed in all patients. Testing took place a median of 7 years after onset of hippocampal damage. In line with previous reports of this patient population (Dalmau and Rosenfeld, 2014; Miller et al., 2017), manual (blinded) segmentation of the hippocampi from high-resolution structural MRI scans confirmed that our patients showed volume loss confined to the left [hippocampaldamaged patients (HPC), 2506 mm$^3$ (mean) ± 394 (SD); control participants (CTL), 3173 mm$^3$ ± 339; W = 4.0, p = 0.002] and right (HPC, 2678 mm$^3$ ± 528; CTL, 3286 mm$^3$ ± 301; W = 8.0, p = 0.01) hippocampus. To rule out pathological differences between patients and controls elsewhere in the brain, an automated voxel-based morphometry (VBM; Ashburner, 2009) analysis was performed on whole-brain T1-weighted MRI images and, in line with previous reports on patients of this sort (Wagner et al., 2015; Finke et al., 2017; Miller et al., 2017), did not result in any significant group differences outside of the hippocampus even at a liberal uncorrected p value of <0.001.

Neuropsychologically, the patients displayed an impairment in immediate and delayed recall on the Logical Memory (short stories) test (Wechsler, 1997), and they recollected significantly fewer episodic (“internal”) but not semantic (“external”) details on the Autobiographical Interview (Levine et al., 2002), as detailed in Table 2. All other cognitive and emotional aspects of cognition were intact in these patients. In summary, these patients seemed to have a selective difficulty in reconstructing internal events. Importantly, their working memory capacity did not differ from that of controls, suggesting that the differences in mind-wandering episodes we report here are unlikely to be attributable to an inability to remember the thoughts.

Twelve healthy control participants also took part (all male, one left-handed, mean age 57.2 (16.6) years, age range from 25 to 77). In addition to comparing the two groups, we ensured that each patient was matched closely to two of the control subjects on sex, age, and general cognitive ability (measured by the Matrix Reasoning and Similarities subtests of the Wechsler Abbreviated Scale of Intelligence–WASI; Wechsler, 1999). There were no significant differences between patients and controls on age, general cognitive ability and on neuropsychological tests assessing semantic memory, language, perception, executive functions and mood (see Table 2 which includes: the Autobiographical Interview (Levine et al., 2002); Wechsler Memory Scale III (Wechsler, 1997); Rey-Osterrith complex figure (Osterrith, 1944); Warrington Graded Naming Test (McKenna and Warrington, 1980; Warrington, 2010); Delis–Kaplan Executive Function System (Delis et al., 2001); Hayling Sentence Completion Test (Burgess and Shallice, 1997); Visual Object and Space Perception Battery (Warrington and James, 1991; Gabrovskia et al., 1996), Hospital Anxiety and Depression Scale (Zigmond and Snaith, 1983)).

**Characterization of hippocampal damage**

High-resolution T2-weighted structural MRI scans of the medial temporal lobes. Five of the patients and 10 of the control participants underwent structural MR imaging limited to a partial volume focused on the temporal lobes using a 3.0 T whole-body MR scanner (Magnetom TIM Trio;
Siemens Healthcare) operated with a radiofrequency (RF) transmit body coil and 32-channel head RF receive coil. These structural images were acquired on a 7.0 tesla MRI scanner, a three-dimensional whole-brain T1-weighted image acquired using the GRAPPA algorithm was used in each phase-encoded direction (AP and RL) with 40 reference lines and a speedup factor of 2. Gradient echoes were acquired with alternating readout polarity at eight equidistant echo times ranging from 2.34 to 18.44 ms in steps of 2.30 ms using a readout bandwidth of 488 Hz/pixel (Helms and Dechent, 2009). The first six echoes were averaged to increase SNR (Helms and Dechent, 2009), producing a T1-weighted image with an effective echo time of 8.3 ms.

For both groups, means (M) and standard deviations (SD) are displayed. HPC = hippocampal-damaged patients; p-value of betweengroup non-parametric Mann-Whitney U tests with significant differences depicted in bold;

## Table 2. Summary of neuropsychological information

| Test                                      | CTRL M (SD) | HPC M (SD) | p value |
|-------------------------------------------|-------------|------------|---------|
| WASH matrix reasoning                     | 13.8 (1.5)  | 13.2 (2.2) | 0.51    |
| WASH similarities                         | 11.8 (2.6)  | 12.8 (1.8) | 0.54    |

For both groups, means (M) and standard deviations (SD) are displayed. HPC = hippocampal-damaged patients; p-value of betweengroup non-parametric Mann-Whitney U tests with significant differences depicted in bold; WASH = Wechsler Abbreviated Scale of Intelligence; Scaled scores of the WASH Matrix Reasoning subtest and WASH Similarities subtest. Autobiographical Interview: int = average number of internal (episodic) details over five memories, ext = average external (semantic) details over five memories.

<sup>a</sup>Of note, autobiographical memory performance of the patients was compared to a separate control group (5 males, 1 female, mean age 55.2 ± 10 years, range 22–69, all right-handed). Scaled scores of the WASH MM = Wechsler Memory Scale III, LMI = logical memory immediate and delayed units and thematic scores, wordlist immediate recall and delayed recognition. Rey = Rey-Osterriech complex figure copy, immediate, and delayed recall. Scaled scores of the Warrington Memory Test for Words and Faces. Scaled scores of the Warrington Graded Naming Test. Scaled scores of the DKEFS = Delis-Kaplan Executive Function System, Letter fluency (FAS), category fluency (animals/bay names), category switch test (fruit/furniture), Stroop word-colour interference test, trails tests, including visual scanning, number sequencing, letter sequencing, number-letter switching and motor speed tests. Scaled scores of the Hayling Sentence Completion Test. VOSP = Visual Object and Space Perception Battery dot counting, cube analysis, and position discrimination subtests; HADS = Hospital Anxiety and Depression Scale. See main test for full test references.
are taken while participants perform low-demanding distractor tasks (Smallwood et al., 2002; Smallwood and Schooler, 2015). Furthermore, using DES, participants are encouraged to describe freely what is on their minds, rather than categorizing thoughts into prespecified classes.

To mitigate any potential difficulties the hippocampal-damaged patients may have had with remembering task instructions over longer timescales, we made a number of adaptations to the original DES protocol. For example, we changed the type of reminder. The reminder is an important tool as it identifies the precise moment of sampling and happens externally to the participant, meaning that the participant does not have to remember to track his own thoughts (Hurlburt and Stuart, 2014). Usually, DES participants carry a beeper and receive frequent sampling reminders while going about their everyday life (Hurlburt and Akhter, 2006). However, we adapted this sampling method to suit an extended experimental setting over 2 days in which patients and controls experienced the same structured days (three MRI scans, various cognitive tasks, breaks, lunches, etc.). In our case, the experimenter provided the external cue for the participant. Equally important as the reminder is the exact time point of the sample. Whereas previous studies have used a random sampling schedule (Hurlburt, 1979; Smallwood and Schooler, 2015), our main goal was to examine the general ability to perceptually decouple and the content of spontaneous thoughts of these rare patients. We, therefore, tried to maximize our chances of catching perceptually decoupled thoughts. Hence, we probed 20 times over the course of 2 structured research days (8 h each) at prespecified times in restful moments. To keep the experimental context of the sampling time points as closely matched across participants as possible, thoughts for all participants were probed in the same rooms of our center, around the same times of day, and in approximately the same experimental situations. This procedure resulted in schedules whereby some samples were separated by several hours (e.g., during which the participant underwent MRI scanning) and other samples that were relatively close in time (e.g., a few minutes). In addition, to ascertain that all participants, especially the patients, could remember time spans long enough to report their thoughts, we asked them to describe two experiments unrelated to the current study shortly after completion. All participants were able to provide accurate accounts of those experiments.

During sampling moments, such as after obtaining consent, and at the beginning of the tea break, the experimenter would allow for a moment of quiet to emerge. That is, the experimenter would fill out some forms or naturally disengage from any conversation. When there was an appropriate time of silence, the experimenter would ask the participant “What were you thinking about just before I asked you?” The participant was encouraged to briefly describe the current thought in one or two sentences. On a prepared note sheet, the participant’s response was written down verbatim. In a follow-up question, the experimenter established whether the thought had been a visual image (if yes, scene or object) or a verbal thought. Then, the experimenter clarified whether that thought had concerned the past, present, or future (and if it had been past or future, how far into the past or future). The sampling procedure lasted no longer than ~1 min to prevent lengthy post hoc elaboration. Finally, divergent from other DES reports, we opted not to train our participants before the start of the study. Although the training may have provided useful guidance in monitoring one’s own thoughts for the control participants, we felt that patients might not find this as beneficial. Therefore, because the experimenter was present for all samples, none of the participants was required to remember the follow-up questions themselves but were instead cued by the experimenter. Of note, control participants
reported equal numbers of decoupled, scene-based thoughts in the first and second half of the samples (first half, 5.8 ± 0.9; second half, 6.3 ± 1.2; W = 11.0, p = 0.42), suggesting that there was no significant training effect. A lack of monitoring was further confirmed by the control participants, because they anticipated the sampling probe for only 3 of a total of 240 sampled thoughts.

Whereas previous research has examined the frequency and content of mind-wandering episodes in healthy participants for features such as goal orientation and emotional valence (Andrews-Hanna et al., 2013, 2014a; Christoff et al., 2016), we focused here on examining the effect of hippocampal damage on the frequency, time range, representational content, and form of mind-wandering, which are key to understanding hippocampal function.

In summary, our adapted sampling protocol permitted us to leverage the naturalistic approach of the typical DES reports that sample over an extended period of time and allowed participants to report their thoughts freely, while equating the daily activities and the sampling moments of patients and control participants to maximize our chances of catching perceptually decoupled thoughts in an experimentally rigorous manner.

**Scoring**

**Perceptually coupled or decoupled thoughts and mind-blanking.** An episode was considered mind-wandering when the response indicated that the mind was disengaged from the external world (perceptually decoupled; Smallwood and Schooler, 2015). For example, the thought “I see your watch” was considered perceptually coupled, whereas the thought “Time is sometimes slow and sometimes fast” was considered perceptually decoupled. In a few instances, patients and control participants reported thinking about nothing (i.e., mind-blanking; Ward and Wegner, 2013). The frequency of this mind-blanking did not differ between the groups (CTL mean, 0.4 ± 0.88; HPC mean, 1.8 ± 2.8; Mann-Whitney U test (MWU) = 23; p = 0.19), and we therefore excluded these samples from further analysis.

**Temporal range.** After each sample, we clarified directly with participants whether that thought concerned the past, present, or future and, if past or future, how distant into the past or future. We also sorted participants’ responses from the “present” category based on the observation that patients and control participants reported very different types of thoughts. Consequently, we classified each mind-wandering episode that was labeled by participants as concerning the present moment as either an atemporal scenario or not, in line with the protocol of Jackson et al. (2013). A mind-wandering episode was considered present related if the thought was perceptually decoupled but concerned the now, e.g., “I’m thinking that you are right-handed” or “I wonder whether I should eat another grape.” On the other hand, a thought was classified as an atemporal scenario if the participant reported a mental event that had no clear temporal direction. For example, a control participant’s thought was, “I noticed this apparatus (EEG box) and I just imagined a picture in my mind in which that box was being used in a horror setting.” By contrast, a patient reported while noticing the same EEG box, “I wonder what this box with all these cables does. But I have no idea.” We display a detailed characterization of the temporal range of mind-wandering episodes in Figure 2. For statistical analysis, thoughts were binned into four main time categories, namely past (any thought related to earlier than the present moment), present (now), future (any thought related to later than the present moment), and atemporal thoughts.

**Representation type.** Thoughts were classified as either semantic or episodic (in line with established methods; Levine et al., 2002; Andrews-Hanna et al., 2014b), and, in addition, whether they contained self-referential thinking or not (Andrews-Hanna et al., 2014a,b). A thought was classified as semantic if it contained mentalization, or general knowledge about the world or the participant. For example, a semantic, self-referential thought of a patient was “I am self-pondering. Am I a creative person?” A thought was classified as episodic if it contained specificity of time and place and a feeling of re-experiencing or pre-experiencing (Tulving, 1983, 2002). For example, an atemporal, episodic, non-self-referential thought of a control was “I’m thinking about my friend. He’s traveling around giving lectures. I imagine an auditorium where the audience is cheering me on.” A thought was classified as atemporal if it had reference to a specific place and time, even if one or both were fictitious (time was more often fictitious). For example, an atemporal, episodic, non-self-referential thought of a control was “I’m thinking about my friend at King’s Cross concourse a few weeks ago. I can see the scene clearly in front of me.” Of note, we also classified thoughts as episodic that had reference to a specific place and time, even if one or both were fictitious (time was more often fictitious). For example, an episodic, self-referential thought of a control participant was “I am remembering a discussion I had with my friend at King’s Cross concourse a few weeks ago. I can see the scene clearly in front of me.” Of note, we also classified thoughts as episodic that had reference to a specific place and time, even if one or both were fictitious (time was more often fictitious). For example, an atemporal, episodic, non-self-referential thought of a control was “I’m thinking about my friend. He’s traveling around giving lectures. I imagine an auditorium and see my friend speaking.”

**Form of thoughts.** We asked participants after each sample whether the thought had been verbal or visual and, if visual, whether it had been a scene or an object. Each thought was sorted into only one of these categories. Some participants reported that some of the visual scenes also contained verbal aspects; however, they regarded the visual scene as being
more dominant. Therefore, these thoughts were classified as scenes. This classification was accomplished in agreement with each participant.

**Interrater reliability**
To avoid potential rater biases, a second rater, who was blind to group membership, scored all thoughts from the patients and the control participants (except for one control dataset that was used as a training set). Interrater reliability was calculated as the direct correspondence between the two raters. That is, thoughts that were scored identically in a category were given a “1”; otherwise, they were given a “0.” The reliability was then established as the sum divided by the total amount of rated thoughts. Therefore, a value of 0.99 indicates that in 99% of samples, the raters were given a “1”; otherwise, they were given a “0.” The reliability was then established as the sum divided by the total amount of rated thoughts. Therefore, a value of 0.99 indicates that in 99% of samples, the raters categorized them identically. The overall agreement between raters ranged between 84 and 99% across the thought categories (i.e., atemporal, 88%; coupled/decoupled, 99%; semantic, 84%; episodic, 85%; self-referential, 87%).

**Statistical analyses**
Since most of the dependent variables did not meet the assumptions for parametric statistics, nonparametric tests were used for all within- and between-group analyses. Within-group analyses with more than two dependent variables were first conducted using Friedman tests (the nonparametric equivalent of repeated-measures ANOVAs) and followed up with two-tailed Wilcoxon signed rank tests (the nonparametric equivalent of paired t tests). Between-group analyses with more than two dependent variables were first conducted using Kruskal–Wallis tests (the nonparametric equivalent of one-way ANOVAs) and followed up with two-tailed Mann–Whitney U tests (the nonparametric equivalent of two-sample t tests). Analyses with two dependent variables were directly compared using two-tailed Wilcoxon signed rank tests (within-group effects) or Mann–Whitney U tests (between-group effects). In all cases, we considered p values <0.05 as statistically significant. For significant results, we also report, where appropriate, the effect size (using nonparametric Cohen’s d), and we show the data of every participant.

**Results**

**Frequency of mind-wandering**
We first examined whether or not patients with hippocampal damage were able to mentally decouple from the current perceptual input (Fig. 1b,c). We found that the percentage of perceptually decoupled thoughts was greater than perceptually coupled thoughts in the controls (W = 78.0, p = 0.0005) and patients (W = 21.0, p = 0.03; Table 3). Notably, we found no difference between the two groups in the frequency of coupled (MWU = 19.5, p = 0.12) or decoupled (MWU = 19.5, p = 0.12) thoughts.

**Temporal range of mind-wandering**
Since mental time travel seems to occur frequently during mind-wandering (Smallwood and Schooler, 2015), we next examined whether the patient and control groups spontaneously thought about the past, present, or future. After each thought sample, we asked participants whether the thought concerned the present moment, past, or future and, if the latter two, how distant was it from the present moment (see Fig. 2 for a detailed visualization of multiple time bins). As described above, we also included an atemporal category in our analyses, comprising thoughts where a participant reported a mental event that had no clear temporal direction.

Examining the results for control participants in the first instance, we found that there was a significant effect of time category (Friedman statistic = 19.99, df = 3, p = 0.0002). Post hoc analyses showed that controls spent more of their mind-wandering time thinking about the past than the present (W = 62.0, p = 0.002) or future (W = 72, p = 0.002). They also spent more time simulating atemporal scenarios than thinking about the present (W = 62, p = 0.01). In contrast, there was no overall effect of time category for patients (Friedman statistic = 6.86, df = 3, p = 0.07).

Direct comparison between the two groups revealed overall differences (Kruskal–Wallis statistic = 31.93,df = 7, p < 0.0001). Post hoc analyses showed that the patients thought less often than controls about past events (MWU = 14.0, p = 0.04, Cohen’s d = 1.1). By contrast, the patients thought more often about the present moment than control participants (MWU = 7.0, p = 0.0034, Cohen’s d = 1.7). There was no difference between the groups in the percentage of future-thinking, which was generally low for both groups (MWU = 18.0, p = 0.09). Finally, we found that controls more often than the patients imagined atemporal events and hypothetical scenarios that concerned a fictitious reality, which was not attached to any temporal dimension (Fig. 2, inset; MWU = 3.0, p = 0.0007, Cohen’s d = 2.1).

**Representation type**
We next investigated what the patients mind-wandered about (Fig. 3; Table 3). Focusing first on the control participants, we found that they reported significantly more episodic than semantic thoughts (W = 78, p = 0.0005) and more self-related than non-self-related thoughts (W = 78, p = 0.0005). The patients

**Table 3. Summary of mind-wandering data**

| Representational type                  | CTL   | HPC   | ρ     |
|---------------------------------------|-------|-------|-------|
| Perceptually coupled                  | 6.8 (7.5) | 13.4 (13.6) | n.s.  |

| Temporal range                        |       |       |       |
| Past                                  | 36.9 (12.7) | 21.2 (16.4) | *     |
| Present                               | 18.9 (8.3) | 32.9 (7.4) | **    |
| Future                                | 15.6 (9.9) | 24.6 (9.2) | n.s.  |
| Atemporal                             | 31.8 (8.7) | 17.8 (5.5) | ***   |
| Represenational type                  |       |       |       |
| Episodic                              | 72.6 (12.4) | 24.8 (14.3) | ***   |
| Semantic                              | 27.4 (12.4) | 75.2 (14.3) | ***   |
| Self-referential                      | 75.2 (10.1) | 75.6 (8.4) | n.s.  |
| Non-self-referential                  | 27.8 (10.1) | 24.4 (8.5) | n.s.  |
| Form of thought                       |       |       |       |
| Scenarios                             | 63.5 (5.4) | 12.3 (11.7) | ***   |
| Objects                               | 9.8 (6.9) | 9.1 (0.9) | n.s.  |
| Words                                 | 26.8 (8.4) | 78.7 (16.2) | ***   |

For both groups, means (percentages) are displayed with SDs in parentheses. P values are for between-group nonparametric Mann–Whitney U tests. *p < 0.05; **p < 0.01; ***p < 0.001. n.s., Not significantly different.
These differences in the experiential form of mind-wandering were confirmed by directly comparing the participant groups (Kruskal–Wallis statistic = 56.33, df = 7, p < 0.0001). Whereas controls reported more visual scenes than patients (MWU = 0.0, p = 0.0001, Cohen’s d = 2.6), patients reported more verbal thoughts than controls (MWU = 0.0, p = 0.0001, Cohen’s d = 2.6), with no difference between participant groups for visual objects (MWU = 30.0, p = 0.59).

**Discussion**

Mind-wandering is pervasive in humans and likely has an important role to play across cognition, influencing processes such as future planning, creative thinking, and problem-solving (Baird et al., 2011, 2012; Andrews-Hanna et al., 2013). Here we showed that patients with hippocampal damage were able to perceptually decouple from the external world and experience spontaneous thoughts. Nevertheless, the small, selective lesions of their hippocampi dramatically affected the nature of their mind-wandering. Whereas healthy participants thought about the past, present, and future, primarily in terms of episodic, detail-rich visual scenes, the patients mainly experienced verbally mediated semantic thoughts anchored in the present. Previous studies have examined episodic thought processes in patients with hippocampal damage using explicit tasks, such as the Autobiographical Interview (Levine et al., 2002) or the scene construction task (Hassabis et al., 2007), that were designed to challenge the patients’ ability. In contrast, our findings show that even when there is no direct cognitive demand, the thought structure of people with hippocampal damage is strikingly different from healthy controls.

We first consider whether our results can be explained by a memory deficit that caused the patients to rapidly forget their mind-wandering thoughts before they could be accurately reported. We do not think this is the case for a number of reasons. First, the patients had intact working memory and could retain task instructions during neuropsychological tests (Table 2) over longer timescales than those in the current study. Second, we asked participants to describe two experiments unrelated to the current study shortly after completion, thus mirroring the timescale of reporting their mind-wandering experiences. All participants, including the patients, were able to provide accurate accounts of those experiments. Third, in previously published studies involving the same patients and control participants using different paradigms, the patients were able to maintain information over time periods that were longer than those required for generating the current mind-wandering samples (McCormick et al., 2016, 2017a). Fourth, our sampling method did not involve any delay or distraction that might have affected the patients, nor did our protocol allow for increased post hoc elaboration on the part of the control participants. Finally, if patients did not remember what they had been thinking about, the frequency of their mind-wandering would have been lower and they would have reported more mind-blanking, which was not the case. Thus, we are confident the patients were able to accurately report what was on their mind within seconds of the sampling cue.

Previous reports have estimated that humans tend to mind-wander ∼30–50% of waking time (Kane et al., 2007; Killingsworth and Gilbert, 2010). Here we report percentages nearer 80–90%. However, we specifically aimed to catch restful periods, and so our higher percentage of mind-wandering thoughts suggests that we were successful at probing time points when mind-wandering levels were high.

Numerous studies have focused on delineating different aspects of inner experiences. For example, self-generated thinking...
(either intentional or unintentional; Seli et al., 2016) typically refers to the ability to mentally decouple from the current perceptual surroundings and generate independent internal thoughts (Smallwood and Schooler, 2015), which is a dichotomous definition that we used in the current study. In reality, these self-generated thoughts align on a continuum ranging from closely task related to totally task unrelated (Smallwood and Schooler, 2015). What was most important for our research question was whether patients could decouple perceptually from their immediate surroundings in a completely task-free context. We found that they were able to do so and that the frequency of their mind-wandering did not differ from that of the control group. This result is especially noteworthy, given a recent study that found reduced frequency of mind-wandering in patients with ventromedial prefrontal cortex (vmPFC) lesions (Bertossi and Ciaramelli, 2016), a brain region with dense functional and anatomical connections with the hippocampus (Andrews-Hanna et al., 2010; Catani et al., 2012, 2013; McCormick et al., 2017b). Although there were differences in the experimental setup between our study and that involving the vmPFC patients, the difference in mind-wandering frequency observed in these two studies might indicate that the vmPFC is critical for the initiation of endogenous spontaneous thought and the hippocampus for its form and content.

At first glance, our finding of group differences in the temporal extent of mind-wandering is not surprising given the difficulty patients with hippocampal damage are known to have with recalling recent and remote episodic memories and imagining the future (Rosenbaum et al., 2008; Kurczek et al., 2015). However, these previous results were based on active and cognitively demanding tasks. To the best of our knowledge, this is the first indication that hippocampal-damaged patients experience reduced mental time travel even in their spontaneous thoughts. Of note, we did not replicate previous reports suggesting a near future-thinking bias in the mind-wandering of healthy participants (Stawarczyk et al., 2011; Song and Wang, 2012; Bertossi and Ciaramelli, 2016). The current experimental procedure and the older age of our participants may have influenced these results (Maillet and Schacter, 2016). For example, instead of sampling during low-demanding computer tasks or in natural environments that may encourage thoughts about the near future (e.g., “Where am I going after I’m finished here?”), we sampled thoughts across a structured day of stimulating research activities. This may have provided more opportunities to think about the recently completed cognitive tasks or MRI scans. In addition, many previous studies have not included an atemporal category of thoughts, and it has been argued that thoughts labeled as future oriented might, in some instances, be more accurately characterized as atemporal (Jackson et al., 2013). Indeed, in line with our results, it has been reported that healthy older adults experience more atemporal than future-oriented mind-wandering episodes (Jackson et al., 2013).

Recently, there have been increased efforts to map the complex cognitive processes that support mind-wandering to specific brain regions. Although it is has been established that the DMN is associated with mind-wandering (Buckner et al., 2008; Andrews-Hanna et al., 2014a; Smallwood and Schooler, 2015), the contributions of specific brain areas within the DMN to mind-wandering remain unclear. Our results provide novel evidence that the hippocampus plays a causal role in episodic mind-wandering. These findings align with recent neuroimaging work that focused on a subsystem of the DMN, of which the hippocampus (and vmPFC) are nodes (Andrews-Hanna et al., 2010), and illustrated that functional and structural connectivity is stronger in individuals who report many detail-rich mental time travel experiences during mind-wandering (Karapanagiotidis et al., 2016; Smallwood et al., 2016). Our results further accord with network analyses in patients with hippocampal damage that showed altered hippocampal–neocortical connectivity patterns (Hayes et al., 2012; McCormick et al., 2014; Henson et al., 2016), which were associated with worse episodic memory capacity (McCormick et al., 2014). Of note, to the best of our knowledge, ours is the first report of a concomitant increase in spontaneous semantic thoughts associated with hippocampal damage. This may help to explain previous findings of increased connectivity between brain areas involved in semantic processing in resting-state fMRI studies involving similar patients (Hayes et al., 2012; McCormick et al., 2014).

In line with previous studies, our results demonstrate that mind-wandering episodes of control participants typically comprise visual imagery (Andrews-Hanna et al., 2013). We expand on existing studies by showing that visual imagery in task-unrelated mind-wandering of healthy controls primarily consists of spatially coherent visual scenes. In striking contrast, the patients with bilateral hippocampal damage no longer reported visualizing mental scenes, relying instead on a verbal thought structure. A scene construction deficit has been implicated in the impaired autobiographical memory and future thinking of patients with hippocampal damage (Hassabis and Maguire, 2007; Maguire and Mullally, 2013; Clark and Maguire, 2016). Our findings support this link between episodic thought and scene imagery. Importantly, this deficit also extends to scene perception tasks (Lee et al., 2005; Aly et al., 2013; McCormick et al., 2017a), suggesting that the lack of mental scenes is not because of faster visual degradation of imagery (Warren et al., 2011), but rather is attributable to an online scene construction problem. Thus, our results strongly suggest that hippocampal-supported scene construction is also central to the content and form of mind-wandering and that without it spontaneous thought seems to be reliant on verbal semantics.

Although the precise definition of mind-wandering is still debated, our results show that selective bilateral lesions to the hippocampus impair perceptually decoupled inner thoughts in specific ways, thus informing the nature of mind-wandering and how it is realized at the neural level. That individuals with hippocampal damage experience mind-wandering but very little detail-rich mental imagery is an important new insight that indicates the hippocampus is not necessary for the instigation of spontaneous thought per se. Instead, it seems to be crucial for processing the form and content of mind-wandering. Our results also speak to the functions of the hippocampus. By showing it plays a causal role in a phenomenon as ubiquitous as mind-wandering, this exposes the impact of the hippocampus beyond its traditionally perceived role in episodic memory, placing it at the center of our everyday mental experiences.
