ABSTRACT

Ices regulate much of the chemistry during star formation and account for up to 80% of the available oxygen and carbon. In this paper, we use the Spitzer c2d Legacy ice survey, complimented with data sets on ices in cloud cores and high-mass protostars, to determine standard ice abundances and to present a coherent picture of the evolution of ices during low- and high-mass star formation. The median ice composition H2O:CO:CO2:H3OH:CH4:NH3:CH3CN is 100:29:29:3:5:5:0.3 and 100:13:13:4:5:2:0.6 toward low- and high-mass protostars, respectively, and 100:31:38:4:–:–:– in cloud cores. In the low-mass sample, the ice abundances with respect to H2O of CH4, NH3, and the component of CO2 mixed with H2O typically vary by <25%, indicative of co-formation with H2O. In contrast, some CO and CO2 ice components, XCN, and CH3OH vary by factors 2–10 between the lower and upper quartile. The XCN band correlates with CO, consistent with its OCN− identification. The origin(s) of the different levels of ice abundance variations are constrained by comparing ice inventories toward different types of protostars and background stars, through ice mapping, analysis of cloud-to-cloud variations, and ice (anti-)correlations. Based on the analysis, the first ice formation phase is driven by hydrogenation of atoms, which results in an H2O-dominated ice. At later prestellar times, CO freezes out and variations in CO freezeout levels and the subsequent CO-based chemistry can explain most of the observed ice abundance variations. The last important ice evolution stage is thermal and UV processing around protostars, resulting in CO desorption, ice segregation, and the formation of complex organic molecules. The distribution of cometary ice abundances is consistent with the idea that most cometary ices have a protostellar origin.

1. INTRODUCTION

Star formation begins with the collapse of an interstellar cloud core to form a protostar, which grows from infall of envelope material and later through an accretion disk, where planets may form. This physical evolution from cores to planetary systems is accompanied by a chemical evolution, which will affect planet and planetesimal compositions. Much of this chemical evolution takes place in icy mantles on interstellar grain surfaces, and the aim of this paper is to consolidate the knowledge of the evolution of ice during star formation using results from the Spitzer Space Telescope mission.

The first ices were detected in the interstellar medium almost 40 years ago (Gillett & Forrest 1973), and from previous work, mostly toward high-mass protostars, H2O, CO, and CO2 ices are known to be common during the cold and dense stages of star formation, with abundances reaching 10−5 nH2. The ice mantles also contain smaller amounts of CH3OH, CH4, NH3, and XCN (e.g., Gibb et al. 2004). CH3OH and other ices are proposed sources of complex organic molecules (Charnley et al. 1992; Garrod et al. 2008; Öberg et al. 2009b) and determining ice abundances and production channels in star-forming regions is therefore of great interest for studies of prebiotic chemistry. Most ices except for CO are predicted to form in situ on interstellar grain surfaces through hydrogenation and oxygenation of atoms and small molecules (Tielens & Hagen 1982). Heat and UV radiation from protostars may result in additional ice processing and Gibb et al. (2004) suggested that some CO2 ice, and all CH3OH and XCN ices form through such processing based on observations toward high-mass protostars with the Infrared Space Observatory (ISO). This has been challenged by observations of abundant CH3OH and XCN ices toward low-mass protostars (Pontoppidan et al. 2003b; van Broekhuizen et al. 2005), where ices are protected from strong UV fields during most of their life time.

Spitzer’s high sensitivity made it possible to observe ices toward low-mass protostars and background stars at 5–30 μm. The c2d Legacy program (Evans et al. 2003) obtained Infrared Spectrograph (IRS) spectra of 50 low-mass protostars (Boogert et al. 2008; Pontoppidan et al. 2008; Öberg et al. 2008; Bottinelli et al. 2010; from now on Papers I–IV), providing an unprecedented sample size that complements the ISO data on high-mass protostars. Additional Spitzer ice observations exist on ices toward background sources, looking through molecular clouds at a range of extinctions (Bergin et al. 2005; Knez et al. 2005;
The Astrophysical Journal, 740:109 (16pp), 2011 October 20

Öberg et al.

Pontoppidan 2006; Whittet et al. 2009; Boogert et al. 2011) and toward protostars in a high-UV environment (Reach et al. 2009).

Because the Spitzer spectrometer had a lower cutoff at \(\lambda = 5\mu m\), complete ice inventories can only be obtained by adding complementary ground-based spectroscopy to cover the strong 3 \(\mu m\) H\(_2\)O, the 4.65 \(\mu m\) CO, the 4.6 \(\mu m\) XCN, and the 3.53 \(\mu m\) CH\(_3\)OH features. The latter feature has been used to validate the use of the 9.7 \(\mu m\) feature to derive CH\(_3\)OH ice abundances (Paper I). The XCN feature has been shown empirically to consist of two components, whose relative contributions to the feature vary from source to source (van Broekhuizen et al. 2005). One of the components can be securely assigned to OCN\(^-\) from comparison with laboratory spectra, while the carrier of the second component, peaking at 2175 cm\(^-1\), is unknown. Suggested carriers of the 2175 cm\(^-1\) component include OCN\(^-\) present in a different ice environment, resulting in a different spectrum, as well as completely different molecules (Pendleton et al. 1999; van Broekhuizen et al. 2004).

In the analysis of astrophysical ice spectra, comparison with laboratory ice spectra is the key, both to identify ice species (such as OCN\(^-\) above) and to characterize the ice morphology; i.e., some ice bands, such as CO and CO\(_2\), cannot be fitted by a single laboratory ice mixture, but seem to trace molecules in two or more ice phases (Tielens et al. 1991; Chiar et al. 1995; Dartois et al. 1999; Paper II). Traditionally the observed spectra have been directly compared to a superposition of pure and mixed ice spectra, characterizing the ice morphology in each source independently (e.g., Merrill et al. 1976; Gibb et al. 2004; Zasowski et al. 2009). The constraints are often degenerate, however, since ice spectral features vary with ice composition, temperature, and radiation processing. To address this, ice bands have instead been decomposed phenomenologically into a small set of unique spectral components (e.g., Tielens et al. 1991; Pendleton et al. 1999; Keane et al. 2001; Pontoppidan et al. 2003a; and Section 2.2). The contributions of the derived components are then used to characterize the spectral bands in all sources in the sample. This method was employed in Papers I and II. Because all observed spectra are decomposed into the same, small number of components, this method provides information on the sample as a whole, i.e., it directly shows which parts of the spectral profile are ubiquitous and which are environment dependent. This is crucial information when assigning a component carrier—without this, the degeneracy is almost always too large to draw conclusions about the structure of the ice from spectral profiles alone.

Building on the analysis in Papers I–IV, this paper aims to establish an ice evolution scenario that also takes into account the present knowledge of ice abundances toward cloud cores (Boogert et al. 2011) and high-mass protostars (Gibb et al. 2004). Section 2 summarizes the sample characteristics. Section 3 presents new ice data for 10 low-mass protostars, followed by ice abundance medians toward low- and high-mass protostars. The variation among the low-mass protostellar abundances are investigated followed by comparison of this ice sample with ices toward high-mass protostars, low-mass protostars in a high-radiation environment, and background stars. The reasons for the abundance variations seen for some ice features are further explored through analysis of spatial differences and correlation studies. Furthermore, new data are used to test previous hypotheses about the carrier(s) of the XCN band. The results are discussed in Section 4 with respect to different ice formation scenarios and ice chemistry in low- versus high-mass star-forming regions.

2. SAMPLE AND ICE FEATURES

2.1. Sample

Spitzer/IRS spectra were obtained for \(\sim 50\) low-mass protostars with ice features as part of the c2d Legacy program (PIDs 172 and 179), a dedicated open time program (PID 20604), and a Guaranteed Time Observations (GTO) program (PI: Houck). All sources were included in Papers II and III on CO\(_2\) and CH\(_4\), while the c2d sources alone were investigated in Papers I and IV.

The Spitzer spectra were complemented by ground-based Keck/NIRSPEC (McLean et al. 1998) and Very Large Telescope (VLT)/ISAAC (Moorwood 1997) L-band spectra of the H\(_2\)O ice 3 \(\mu m\) feature. In addition, the combined sample partly overlaps with a 3–5 \(\mu m\) VLT survey of CO and XCN ices toward low-mass protostars (Pontoppidan et al. 2003b; van Broekhuizen et al. 2005), and additional CO observations were obtained with Keck/NIRSPEC (Paper II). The VLT survey contains many sources in Ophiuchus, for which the Spitzer data are taken from GTO programs. These sources are key for a comprehensive investigation of how the XCN complex, composed of OCN\(^-\) and potentially a second carrier, relates to other ices. The reduction of the spectra to obtain abundances are described in the individual c2d papers and the additional GTO sources have been reduced using an identical procedure to those presented in Papers I and IV.

The low-mass sample is complemented with nine ISO sources, representative of high-mass protostars, from Gibb et al. (2004) which were re-analyzed in Papers I–III to ensure that the low- and high-mass ice abundances are consistently derived using the same component analysis and band strengths. The sources were not included in Paper IV, and NH\(_3\) abundances are therefore taken from Gibb et al. (2004). In summary, our sample consists of 63 young stellar objects (YSOs) that have been analyzed in a homogenized way. When compared with ice abundances toward background stars from Knez et al. (2005) and Boogert et al. (2011), this sample spans all evolutionary stages from molecular clouds to disks and six orders of magnitude in stellar luminosities and a range of star-forming environments.

2.2. Ice Features

Figure 1 shows the main ice features seen toward background stars and protostars with the identifications of different bands to H\(_2\)O, CO, CO\(_2\), CH\(_3\)OH, NH\(_3\), CH\(_4\), and OCN\(^-\) ices marked. H\(_2\)O column densities are derived from the 3 \(\mu m\) band whenever such data are available; otherwise, the librational band (10–30 \(\mu m\)) is used. CH\(_3\)OH and NH\(_3\) abundances are generally derived from the 9–10 \(\mu m\) bands. OCN\(^-\) abundances are derived from one of the two components (centered at 2163 cm\(^-1\)) that together make up the XCN band (the total band centered at 4.62 \(\mu m\) next to the CO feature). The OCN\(^-\) identification is based on laboratory spectra. The abundance of the second XCN carrier (associated with the “2175 cm\(^{-1}\)” band) is derived assuming the OCN\(^-\) band strength.

The CO and CO\(_2\) spectral features can be decomposed into a number of components corresponding to CO and CO\(_2\) in different ice mixtures (Pontoppidan et al. 2003b; Paper II). CO is decomposed into three components corresponding to pure CO ice, CO mixed with CO\(_2\) (CO:CO\(_2\)), and CO mixed with H\(_2\)O ice (CO:H\(_2\)O). CO\(_2\) is similarly decomposed into four components corresponding to pure CO\(_2\) ice, CO\(_2\) mixed with CO (CO\(_2\):CO), CO\(_2\) mixed with H\(_2\)O ice (CO\(_2\):H\(_2\)O), and a shoulder which has
been associated with CO₂ mixed with CH₃OH (Dartois et al. 1999).

More tentative identifications of spectral bands to HCOOH, NH₃⁺, CH₂CH₂OH, and CH₂CHO are also marked in Figure 1. Most of these tentative identifications are found in a complex band between 5 and 7 $\mu$m. To constrain the carriers of this band it was decomposed into five different components (C1–C5) after subtraction of the contribution from H₂O ice in Paper I. C1 and C2 make up the 6 $\mu$m band, C3 and C4 the 6.8 $\mu$m band, and C5 is a broad, underlying feature that covers the entire 5–7 $\mu$m region. From comparison with laboratory ice spectra, C1 has been identified with HCOOH and H₂CO, C2 with HCOO⁻ and NH₃, C3 with NH₂⁺ and CH₂OH, C4 with NH₂⁺, and C5 with warm H₂O and anions (Paper I).

3. RESULTS

Figure 1 shows the similar 3–20 $\mu$m spectra toward protostars spanning orders of magnitude in luminosities, suggestive of a partly shared ice formation history during all types of star formation. The spectra are not identical, however, and median abundances of identified ices toward low- and high-mass protostars are presented in Section 3.2. Ice abundance variations toward low-mass protostars are further investigated in Section 3.3 to constrain which ices form together with H₂O and which do not. In Section 3.4 the low-mass sample is contrasted with ice abundance distributions toward high-mass protostars to test the significance of any differences noted in Section 3.2. Section 3.5 continues with a comparison of ice distributions between clouds and protostars to constrain which ices require protostellar processing to form. Section 3.6 presents an analysis of spatial variations in ice abundances, both on large scales between clouds, and on small scales within a single core. Finally, ice correlations are used in Section 3.7 to provide further constraints on XCN formation, and H₂O ice anti-correlations are presented to investigate which ices form in competition with H₂O.

3.1. New Ice Abundances in Ophiuchus

To enlarge the sample of low-mass sources with available XCN data, a set of GTO data in Ophiuchus was analyzed in the same way as the c2d sources. The five components, C1–5, from Paper I are fitted to the 5–7 $\mu$m complex with their peak optical depths as free parameters. The NH₃ and CH₂OH abundances toward the same sources are determined from their 9.0 and 9.7 $\mu$m features, using a fourth-order polynomial to remove the underlying silicate feature (Paper IV). After continuum subtraction, column densities are derived by fitting two Gaussians to the observed spectra around the expected band positions and using the same band strengths as in Paper IV (Table 1). The flux and optical depth spectra are shown in Appendix A together with fitted peak positions and band widths. While NH₃⁺ is not explicitly discussed here except in the context of the N-budget, maximum abundances for the Ophiuchus sources can be extracted from Table 1 using the same conversion factor as in Paper I. HCOOH abundances are not reported, since the previously used feature may have a significant contribution from other carriers (Appendix B). The presence of a feature at 7.25 $\mu$m is in itself evidence for the formation of complex ices, even though its dominating carrier (probably HCOOH or CH₂CH₂OH) is speculative.

3.2. Median Abundances

Figure 2 shows the median ice abundances with respect to H₂O ice for low- and high-mass protostars, calculated from Papers I–IV and from the new Ophiuchus values reported in Table 1. All ice abundances are expressed with respect to H₂O because H₂O ice forms early during star formation, is the most abundant ice, and has a high sublimation point. The median values are calculated: (1) using only the detections and (2) using the Kaplan–Meier (KM) estimate of the survival function. The latter is a non-parametric procedure that takes into account the constraints provided by upper limits. When calculating the KM estimate, the detections and upper limits are ordered from low to high and the upper limits are given the values of the nearest lower detections. For example, in a sample of four detections of 0.5, 1, 3, and 4 and an upper limit of <2, the upper limit is treated as a detection of 1. The KM estimate and how to apply statistical tests on it is reviewed by Feigelson & Nelson (1985). The medians calculated from the KM estimate provide more accurate descriptions of ice populations with significant upper

Table 2
Typical Ice Abundances toward Low- and High-mass Protostars and Background Stars

| Ice Feature | Low Mass | High Mass | Background |
|-------------|----------|-----------|------------|
| H₂O         | 100      | 100       | 100        |
| CO          | 29       | 13        | 31         |
| CO₂         | 29       | 13        | 38         |
| CH₃OH       | 3        | 4         | 4          |
| NH₃         | 5        | 5         | 5          |
| CH₄         | 5        | 2         | 3          |
| XCN         | 0.3      | 0.6       | 0.6        |

Note. *XCN implies a band component securely identified with OCN⁻ and the nearby 2175 cm⁻¹ component, which this study suggests is also due to OCN⁻.

Ice abundance variations between different sources depend on how sensitive the ice formation and destruction pathways are to the local environment. Investigating protostellar abundance variations thus puts constraints on when and where different ices form (variations are not dominated by reported abundance uncertainties from fitting the observed spectra). Figure 3 demonstrates that some ice abundance distributions are skewed with uncertainties from fitting the observed spectra). Figure 4. Histograms of total ice abundances toward low-mass protostars (red) and high-mass protostars (black). For low-mass NH$_3$ abundances, the solid filled histograms are from Paper IV using a silicate template to extract NH$_3$ and the contoured histograms are from Paper IV and Table 1 when using a polynomial to fit the local continuum around the NH$_3$ feature.

(A color version of this figure is available in the online journal.)

Figure 5. Histograms of CO and CO$_2$ components, otherwise as in Figure 4.

(A color version of this figure is available in the online journal.)

CO and CO$_2$ ice components have the broadest distributions, consistent with their expected dependence on the protostellar envelope temperature for ice evaporation and segregation. The 5–7 μm components, C1–5, span the full range of variations observed among the identified ice components, including the previously noted narrow C3 distribution (Paper I).

Protostellar ice heating was explored in Papers I and II as explanations for observed abundance variations, using pure CO/CO$_2$:H$_2$O and pure CO$_2$/CO$_2$:H$_2$O as diagnostics of the amount of moderate ice heating, and H$_2$O/silicate as a probe of complete ice sublimation. Correlations between H$_2$O/silicate and the different C1–5 components are extensively discussed in Paper I and by Boogert et al. (2011) for protostars and background stars. The main conclusion was that C3/C4 does depend on ice sublimation, supporting its identification with low- and high-temperature NH$_4^+$ salts.

Moderate ice heating is predicted to reduce the abundances of volatile ices (decreasing the pure CO abundance), segregate previous ice mixtures (resulting in pure CO$_2$), drive ice crystallization, activate acid–base chemistry, and cause diffusion of ice radicals and thus the formation of more complex species. None of the ice abundances in this study are, however, correlated with either ice temperature tracer (not shown) except for the previously found C5/H$_2$O correlation with pure CO/CO$_2$:H$_2$O (Paper I). Moderate (transient) ice heating alone seems to play a minor role in simple ice formation. This result does not exclude that the combined differences in temperature and UV radiation around low- and high-mass protostars result in different ice chemistries. Whether this is the case is the topic of next section.

3.4. Low- versus High-mass Protostars

Figures 4–6 show that many ices are similarly distributed toward low- and high-mass protostars, but as noted in Section 3.2,
the total CO2, CO, and CH4 abundances are lower toward the high-mass sources. Figure 5 reveals that the difference in CO2 abundances between low- and high-mass stars is due to a difference in the CO2:H2O ice component, which typically dominate the spectra toward low-mass sources (Paper II). All CO components are centered around a lower value toward high-mass protostars compared to low-mass protostars. Among the C1–5 components, C4 seems more abundant toward high-mass protostars.

The significance of the visual differences in Figures 2 and 4–6 and other proposed differences between low- and high-mass protostars can be evaluated statistically. Kruskal–Wallis one-way analysis of variance by ranks is a non-parametric method to test the equality of medians in two or more groups. The null hypothesis χ² statistic. The similar test (the logrank test) was run in R using the previously calculated KM estimates and the function survdiff. The results are consistent with the Kruskal–Wallis test, except that CH4 is different in low- and high-mass stars at the 98% confidence level when including upper limits.

In the above analysis, all low-mass protostars are situated in star-forming regions without any nearby massive stars. It is therefore difficult to disentangle which differences are intrinsic to the low- versus high-mass star-forming processes and which differences depend on the local radiation environment. IC 1396A, known as the Elephant Trunk Nebula, is a dense globule, excited by the 4 Myr old O6 star HD 206267. Ice observations—H2O, CO2, and C1–5—toward four low-mass protostars are presented by Reach et al. (2009). The C3/C4 ratio toward these protostars resembled the ratio found toward high-mass protostars, suggesting that the ice evolution around low-mass protostars depends on the external radiation environment. Figure 7 shows a histogram comparison for the CO2 and C1–5 components (including upper limits) toward low-mass protostars (red contours), high-mass protostars (black contours), and the four IC 1396A sources (red solid).

3.5. Protostars versus Background Stars

Comparisons between protostars and background stars provide direct limits on which species form before the protostar turns on and starts to heat and irradiate its surroundings. Tables 2 and 3 lists the medians of species detected toward background stars in Serpens and in individual cores (Knez et al. 2005; Boogert et al. 2011). For the isolated core sample, we only use those targets with well-known H2O column densities from 3 μm observations. The upper limits on CH4, NH3, and OCN− are generally too high to be useful and there are only a few cases where limits are below 3 μm.

The background star medians are based on detections alone, since applying survival analysis shows that including upper limits does not constrain the medians further.
handful of CO ice observations. C1–5, CO2, and CH3OH are, however, detected in a larger number of sources and can be used to compare cloud and protostellar ices.

Previous ice studies toward Taurus revealed a lower CO2 ice fraction in clouds compared to in low-mass protostellar envelopes (Whittet et al. 2007; Paper II) which together with laboratory studies have encouraged hypotheses of CO2 formation from energetic processing of CO ice around protostars (e.g., Ioppolo et al. 2009). Similarly, CH3OH ice has been proposed to be a product of protostellar UV ice processing (Gibb et al. 2004). Figure 8, using data from Boogert et al. (2011), shows that there is no evidence for different CO2 and CH3OH ice abundances toward protostars and background stars. Applying the Kruskal–Wallis and Keplar–Meier-based tests confirm this lack of a difference in ice composition between our protostellar and cloud sources. Figure 8 also shows the clear difference between Taurus CO2 ice abundances from Whittet et al. (2007) and our background star ice sample. From this difference, ice abundances toward Taurus background stars are not good templates for ice abundances toward average cloud cores.

In summary, observable ices, except for pure CO2 ice and the C5 component, are present at the same abundances in the prestellar and protostellar phase. Most prestellar ice abundance variations reported in Section 3.3 must then be due to differences between clouds and to different prestellar ice formation processes, rather than thermal and UV processing by the protostar.

### 3.6. Spatial Differences within the Low-mass Protostellar Sample

#### 3.6.1. Cloud-to-cloud Variations

Variations in ice formation and destruction efficiencies in the prestellar stage may be associated with different cloud structures and initial chemical conditions in different star-forming regions. This is investigated by dividing the low-mass prestellar sample into six groups with sources belonging to the star-forming associations in Ophiuchus, Serpens, Corona Australis, Perseus, Taurus, and a collection of smaller associations. Kruskal–Wallis tests show that when considered as a whole, the ice abundance medians are statistically indistinguishable between these groups. This is consistent with a Principal Component Analysis in Öberg (2009), which revealed no differences between the different clouds when simultaneously considering all ice abundances.

Cloud-to-cloud variations can also be tested for specific ice components. CO2 ice abundences in clouds were shown above to be unusually low toward Taurus, while too few CO measurements toward background sources outside of Taurus exist to determine whether CO is lower than expected as well. Testing the CO and CO2 protostellar differences between the clouds may reveal whether prestellar differences are carried over into the protostellar phase. CH3OH is another ice that has been observed to be spatially variable (Pontoppidan et al. 2004; Boogert et al. 2011). Differences in the pure CO ice component and the CO2 shoulder (often assigned to CO2:CH3OH interactions) between the clouds are indeed statistically significant at a >98% confidence level, while all other CO and CO2 components and CH3OH are not. The significant differences exist between the low abundances toward Taurus and the smaller associations on one hand, and the more “normal” abundances toward the other clouds (Table 4).

The difference between Taurus and the other clouds is important since much of the current ice paradigm is based on analysis of Taurus sources (e.g., Whittet et al. 2007). The low pure CO ice abundances may also explain the low CH3OH ice upper limits toward Taurus, since CO freezeout is a pre-requisite for CH3OH ice formation without energetic radiation (Cuppen et al. 2009) and a low pure CO ice abundance may indicate that catastrophic CO freezeout has not taken place. In summary, some CO ice abundance differences seem to be explained by large-scale differences in cloud environments, but overall most cloud and prestellar ice formation variability must be due to more local effects than to cloud-to-cloud variation. Both from cloud and prestellar ice abundances, Taurus stands out and care should hence be taken in using Taurus trends as a basis for general conclusions on ice evolution during low-mass star formation.

#### 3.6.2. An Ice Map toward the Oph-F Core

Within single cloud cores, ice maps may reveal production and destruction pathways that depend on the local environment. An ice map of protostars in the Oph-F core has been used previously to show that the total CO and the CO:H2O abundances decrease monotonically away from the central core (Pontoppidan 2006). The lines of sight probe primarily the dense quiescent core, rather than ice in the prestellar envelopes, and the spatial trends were interpreted as catastrophic freezeout of CO in the prestellar stage once a certain density and temperature is reached. Figure 9 shows that the order-of-magnitude increase in CO ice with respect to H2O toward the core is accompanied by an increase in CO2:CO. In contrast, the CO2:H2O ice component is almost constant across the core. The XCN band (the 2175 cm−1 feature—OCN− is not detected) is the only other species that increases monotonically toward the densest part of Oph-F. CO2:CO and the 2175 cm−1 band thus appear directly related to CO freezeout. No trend with distance to the core center is seen for any other ice component and is also not expected.
for ices forming early during cloud formation (e.g., CH₄ and NH₃), which are independent of cloud core timescales and CO freezeout, or of species dependent on protostellar heating (e.g., pure CO₂ ice), or of components with potentially multiple carriers, such as the C1–5 bands. CH₃OH is only detected toward one of the sources and no trend can thus be extracted. Still, the Oph-F map suggests that CO freezeout followed by a CO-driven ice chemistry may account for large prestellar ice variations.

3.7. Protostellar Correlation Studies

The trends found for the Oph-F core are here explored for the entire protostellar sample through correlation studies especially between CO chemistry products and H₂O ice column densities, and between XCN, and CO and CO₂ ice components.

3.7.1. Dependencies on H₂O Ice Column

In individual cores, the H₂O column density has been shown to correlate well with dust extinction, assumed to trace the total dust mass and H₂ column (Whittet et al. 1988; Pontoppidan et al. 2004). This implies that the average abundance of H₂O ice per dust grain is constant across the core. In an arbitrary line of sight, the total H₂O ice column density depends on both the column density of dust grains and on the average number of monolayers of H₂O ice on each dust grain. If variations in the H₂O column density across the sample are dominated by the line-of-sight fraction of high-density material, ices dependent on CO freezeout are expected to correlate with H₂O column density, since CO freezes out catastrophically at high densities (Section 3.6.2). If instead variations in the H₂O column density across the sample are dominated by the H₂O abundance on each grain, the main observable trend should be that ices that form in competition with H₂O anti-correlate with the H₂O column density.

In theory, the dust column density can be estimated from the optical depth of the 9.7 μm silicate feature or from the continuum extinction. Because of a number of practical complications we do not attempt to normalize the H₂O column density to the dust column, however. First, toward protostars, the silicate absorption can be filled in by an unknown amount of silicate emission from the warmer parts of the envelope. Second, continuum extinction estimates are affected by uncertainties in the intrinsic protostellar spectral energy distributions. Third, while the 9.7 μm band correlates well with the near-infrared color excess, the relations vary in different environments by factors of two (Chiar et al. 2007; Boogert et al. 2011), possibly because of variations in the grain size distribution or even variations in the grain composition (van Breemen et al. 2011). And fifth, the contribution of unrelated, iceless foreground dust is often unknown.

There are no significant positive correlations (at the 95% confidence level) between H₂O and any ice abundance, X/H₂O, when applying Spearman’s rank correlation test (Spearman 1904) to the low-mass protostellar sample; rank correlation tests are more robust to outliers compared to most parametric correlation tests and make no assumptions about whether the correlation is linear or nonlinear. Figure 10 shows that, instead, six ice components—CH₄, CO₂:CO, the CO₂ shoulder, CO:H₂O, CO:CO₂, and C₄—are inversely correlated with the H₂O column density at the 97%–99% confidence level. C₄ has been associated with NH₄ salts and its anti-correlation with H₂O may be explained by an increasing salt fraction with ice sublimation because salts have higher sublimation temperatures than H₂O ice (Paper I). This scenario cannot, however, explain the other anti-correlations, since CH₄, CO, and CO₂ are all more volatile than H₂O.

The CO-related anti-correlations may be a result of competitive formation of H₂O and CO; the more oxygen that is bound
The Spearman’s rank correlation test is not yet implemented for censored data. Panel (e) finally confirms previous claims in van Broekhuizen et al. (2004) that the relative importance of the OCN− feature and the 2175 cm−1 feature depend on ice processing, measured here by the pure CO/CO2:H2O ice ratio.

These correlations are indicative of a CO-related, single carrier of the entire XCN band with a spectral profile that depends on the environment. The simplest explanation is that OCN− is responsible for the entire XCN band (i.e., both the “OCN− component” and the 2175 cm−1 component) and that the two components are due to OCN− in a volatile (CO-rich)

 Figure 11. Panels (a)–(d) show correlations between XCN and CO ice components for low-mass protostars (red diamonds) with high-mass protostellar abundances shown for comparison (black stars). Panel (e) shows the relationship between an ice-heating tracer and the two XCN components. Thin symbols denote upper limits.

(A color version of this figure is available in the online journal.)

As stated in Section 1, the XCN band is composed of two components, peaking at 2165 cm−1 (OCN−) and at 2175 cm−1. Toward the Oph-F core, the 2175 cm−1 component is spatially correlated with CO, CO2:CO, and CO:H2O. These correlations were explored in the whole low-mass sample, and Figure 11 shows that the 2175 cm−1 component is significantly correlated with CO and CO2:CO (95% confidence with Spearman’s rank correlation test) and the correlation is even stronger (>99%) when the high-mass sources are added. The complete XCN band is not correlated with either of these components, but it is significantly correlated with the less volatile CO:H2O component (95% level). Panel (e) finally confirms previous claims in van Broekhuizen et al. (2004) that the relative importance of the OCN− feature and the 2175 cm−1 feature depend on ice processing, measured here by the pure CO/CO2:H2O ice ratio.

4. DISCUSSION

4.1. C-, O-, and N-budget

The amount of C, O, and N that are typically bound up in ice mantles is important for the life cycle of the elements in the interstellar medium. The total (refractory + volatile) C, O, and N abundances in the solar neighborhood are 2.1, 5.8, and 0.58 × 10−5 per hydrogen nucleus, respectively (Przybilla et al. 2008). The fractional C, O, and N abundance in ices with respect to these total C, N, and O abundances are calculated from the presented ice abundances with respect to H2O ice together with literature values of the H2O abundance with respect to hydrogen. Pontoppidan et al. (2004) and Boogert & Ehrenfreund (2004) modeled the H2O abundance toward four of the low-mass protostars in the sample and found nH2O = 4.9 ± 0.7 × 10−5 nH. Toward high-mass protostars, the H2O abundance can be estimated using the relations Aν/ν0.7 = 9 and nH/AV ∼ 1.9 × 1021 cm−2 mag−1 (Roche & Aitken 1985; Bohlin et al. 1978). It is important to note that this method only provides a crude estimate since the silicate feature is affected both by emission and grain growth; a recent grain model result in a conversion factor that is 30% lower for dense clouds (Evans et al. 2009). Using the values in Gibb et al. (2004) for W33A, NGC 7538 IRS 9, Mon R2 IRS 3, and S140 IRS 1 (covering the range of observed ice processing) results in an H2O abundance of (5.0 ± 1.9) × 10−5 nH. A mean H2O abundance of 5 × 10−5 nH (i.e., 10−4 nH2) is therefore assumed for both low- and high-mass protostars.

The O abundance in the ice is calculated from (xH2O + xCO + 2 × xCO2 + xCH2OH + xXCN) × nH2O, the C abundance from (xCO + xCO2 + xCH2OH + xCH3 + xXCN) × nH2O, and the N abundance from (xNH2 + xXCN + xN2H+) × nH2O, where xν is the abundance of ν with respect to H2O. The median upper limit on NH2+ is calculated from the total optical depth of the C3 and C4 components, using the FWHM of 0.195 and 0.292 μm, respectively, from Paper I and a band strength of 4.4 × 10−17 cm from Schutte & Khanna (2003).

The median percentages of C, O, and N bound up in ices, calculated from the ice abundances in Table 2, are listed in Table 5. On average 15% of the total (refractory + volatile) C, 16% of the O, and 10% of the N reside in ices toward low-mass protostars. Toward high-mass protostars, the same calculation yields 12% of the O, 8% of the C, and up to 12% of the N atoms. The differences in the amount of C and O are due to the low CO and CO2 abundances toward high-mass protostars.

Table 5 also lists the amount of volatile or non-refractory amounts of C and O that are in ices. In the solar neighborhood, the non-refractory O abundance is 3.2 × 10−4 per N H (Meyer et al. 1998) because a large fraction of O is bound up in silicates and is therefore not available for ice formation (e.g., Whittet 2010). Out of this available O, 34% is bound up in ices toward low-mass protostars, and 25% toward high-mass stars. The
fraction of C in refractory material is less well constrained, but assuming a non-refractory C abundance of $\sim 1 \times 10^{-4}$ (Weingartner & Draine 2001) results in 27% of the available C found in ices toward low-mass protostars and 14% toward high-mass protostars.

The above numbers all relate to the median ice abundances in the sample. The extreme ice sources may, however, provide more information on whether ice formation is limited by the elemental abundances. IRS 51 and NGC 7538 IRS 9 are calculated to be the most ice-rich sources in the sample, when still assuming an H$_2$O ice abundance of $5 \times 10^{-5}$ with respect to n$_{H_1}$. Especially in the case of IRS 51, the amount of O and C found in the ices approaches the abundances of non-refractory O and C (Table 5).

It is important to note that additional O and N may be hidden in the ice in the form of O$_2$ and N$_2$. Direct constraints on O$_2$ ice abundances are high, 50%–100% with respect to CO ice, and constraints from O$_2$ interactions with CO ice are of a similar order (Ehrenfreund et al. 1992; Vandenbussche et al. 1999; Pontoppidan et al. 2003b). O$_2$ ice is, however, unlikely to be abundant from the low upper limits on O$_2$ in the gas phase; it is orders of magnitude less abundant than CO and since the two molecules have similar freezeout and desorption properties it is unlikely that O$_2$ is differently partitioned between ice and gas compared to CO (Goldsmith et al. 2000; Pagani et al. 2003; Fuchs et al. 2006).

### 4.2. Ice Evolution: Early and Late Prestellar Ice Formation

Toward low- and high-mass protostars alike, the ices are dominated by H$_2$O, followed by CO$_2$ and CO (Section 3.2). C and O are expected to react similarly with hydrogen. The low abundance of CH$_4$ therefore implies that most C is not in atomic form when the bulk of the H$_2$O ice is forming from O early in cloud formation or at low extinctions (Region 1. in Figure 12). A fast conversion of C into CO is also consistent with the CH$_4$/H$_2$O versus H$_2$O anti-correlation toward lines of sight with low H$_2$O column densities (Section 3.7); it suggests that CH$_4$ forms more efficiently in the very beginning of H$_2$O formation compared to when the bulk of H$_2$O ice forms at slightly higher extinctions. The bulk of H$_2$O formation is instead associated with continuous formation of CO$_2$, probably from CO+OH (Oba et al. 2010; Ioppolo et al. 2011); the CO$_2$/H$_2$O abundance barely varies from source to source in the low-mass protostellar sample (Section 3.3). H$_2$O and CO$_2$ ice mapping confirms this scenario (Bergin et al. 2005), as do the similar CO$_2$ abundances toward cloud cores and protostars (Section 3.5). Most CO that is frozen out in this phase must be converted into CO$_2$.

From its small abundance variations, NH$_3$ is also inferred to form early with H$_2$O (Section 3.3). The C$_3$ component may be associated with this stage as well and its identification with NH$_3$$^+$ suggests that there exists a large amount of strong acids that can protonate NH$_3$ in cold ices (van Broekhuizen et al. 2004). Anions are notoriously difficult to observe in the ice, however, and thus gas-phase observations of non-thermally evaporated ices at the edges of clouds probably offer the best opportunity to confirm their existence. It is promising that HCOOH has been detected toward translucent clouds (Turner et al. 1999) and a more comprehensive study focusing on gas-phase HCOOH and other acids toward cloud edges, where ice formation has begun and photodesorption is efficient, is warranted.

At some point the CO/O ratio becomes large enough that most frozen-out CO is no longer converted into CO$_2$, and H$_2$O is no longer the most efficiently formed ice. We mark this as the breaking point between early H$_2$O-dominated and late CO-driven prestellar ice formation. The ices that form in this later stage (Region 2. in Figure 12) are not expected to co-vary with H$_2$O, but rather depend on the CO-freezeout efficiency. The latter is both temperature and density dependent and may vary greatly depending on cloud structure, cloud collapse timescales, and local radiation environment. This explains why many identified ice and ice components that are definitely present during the prestellar stage (e.g., CH$_3$OH) have abundances that vary by orders of magnitude with respect to H$_2$O (Sections 3.3 and 3.5) both locally in a single core and when comparing different cloud complexes. In addition, the anti-correlation between H$_2$O ice and the abundance of several CO ice components suggest that the time available for this CO-based chemistry decreases when a longer time is spent in the H$_2$O ice formation stage, where O is converted into H$_2$O and CO$_2$-H$_2$O ices (Section 3.7).

CO$_2$:CO, CO-H$_2$O, and the OCN$^-$ feature are all associated with this CO ice chemistry (Section 3.5). CO$_2$:CO correlates with CO freezeout in the Oph-F ice map, demonstrating a second, later production pathway of CO$_2$. CO$_2$ may still form from OH+CO, but at later stages CO is more abundant than O, resulting in sparse H$_2$O formation compared to CO and thus in a CO-rich CO$_2$ ice (see Garrod & Pauly 2011 for a similar discussion from a theoretical point of view). From the correlation studies in Section 3.7, OCN$^-$ seems to similarly require CO freezeout and may form from CO+NH, followed by proton transfer.

CH$_3$OH and H$_2$CO can form from hydrogenation of CO (Cuppen et al. 2009) and should also depend on CO freezeout levels. There is no strong correlation between CH$_3$OH and CO, however. The CO to CH$_3$OH conversion efficiency thus varies in different lines of sight, probably dependent on the H/CO ratio, which may vary with density and collapse time (Cuppen et al. 2009) and cosmic ray flux (Boogert et al. 2011). Ices are continuously exposed to cosmic rays and cosmic-ray induced UV photons (Shen et al. 2004) and other “late” ice features may also depend on cosmic rays, directly or indirectly. In general, observed ice features can, however, be explained by an early ice chemistry phase characteristic of hydrogenation of atoms, followed by atom-addition reactions in a CO-dominated ice phase.

### 4.3. Ice Evolution: The Protostellar Stage

Though much of the observed ice evolution can be explained by prestellar processes, some ice features are formed or de-
Ice dominated by CO and CO$_2$ ice (Section 3.3), whose variations are best explained by protostellar heating evaporating CO and CO$_2$ containing ices (Paper II; Oberg et al. 2009a). This last and most source-dependent ice chemistry phase is also predicted to result in complex ice formation that requires ice heating for diffusion of large radicals (Garrod et al. 2008; Oberg et al. 2009b). The spectra observed to date do not allow for definitive assignments to any specific complex species, the presence of, e.g., a feature at 7.25 μm belonging either to H$_2$COH or CH$_3$CH$_2$OH demonstrates that some complex organic ices are forming efficiently in the prestellar or protostellar stage.

Most of the observed differences between low- and high-mass protostars can be explained by protostellar heating evaporating CO and CO$_2$ ice and distilling or segregating CO$_2$-containing ices (Paper II; Oberg et al. 2009a). This last and most source-dependent ice chemistry phase is also predicted to result in complex ice formation that requires ice heating for diffusion of large radicals (Garrod et al. 2008; Oberg et al. 2009b). While the spectra observed to date do not allow for definitive assignments to any specific complex species, the presence of, e.g., a feature at 7.25 μm belonging either to H$_2$COH or CH$_3$CH$_2$OH demonstrates that some complex organic ices are forming efficiently in the prestellar or protostellar stage.

In the low-mass protostellar sample, there is no correlation between pure CO$_2$ ice abundance and the total envelope mass as traced by H$_2$O ice (Section 3.7.1). There is thus no evidence that variations in pure CO$_2$ fractions can be explained by variable envelope sizes (toward high-mass protostars, envelope temperatures and sizes anti-correlate; see van der Tak et al. 2000). Rather large amounts of pure CO$_2$ toward some low-mass protostars may be a remnant of past luminosity outbursts that heated up the envelope beyond its low-accretion temperature, since ice segregation is an irreversible process (Kim et al. 2011a, 2011b). Episodic accretion resulting in luminosity outbursts has been invoked to explain the luminosity problem of low-mass YSOs, i.e., the observation that most YSOs are significantly less luminous than predicted by protostellar evolutionary models with steady accretion (Evans et al. 2009; Dunham et al. 2010).

There is no evidence for a higher CH$_3$OH or OCN$^-$ content toward high-mass stars, except for the cases of overabundant OCN$^-$ toward W33A and very abundant CH$_3$OH toward GL7009S (Dartois et al. 1999); thus, neither species seems to require stellar UV irradiation or thermal processing to form at typical abundances. The composition of the XCN band varies on average between low- and high-mass objects, but as discussed above the carrier is probably dominated by OCN$^-$ in both cases. Of the remaining ice components C4 and C5 seem to have higher abundances toward the high-mass protostars, indicative of at least a partial formation pathway involving heat or UV irradiation or both, in agreement with the analysis in

![Figure 12. Key ice reactions during the different stages of cloud and star formation, where 0. corresponds to cloud edges where UV photons can penetrate, 1. the early stages of dense cloud formation, 2. the later formation of cloud cores, and 3. the protostellar envelope. Ice formation begins in 1. with hydrogenation of atoms resulting in an H$_2$O dominated ice with a high CO$_2$ concentration (CO$_2$:H$_2$O). At later times CO freezes out catastrophically, resulting in a second layer where CO$_2$ combines with CO to form CO and pure CO$_2$ ice (Section 3.3), whose variations are best explained by protostellar heating evaporating CO and CO$_2$ containing ices (Paper II; Oberg et al. 2009a). This last and most source-dependent ice chemistry phase is also predicted to result in complex ice formation that requires ice heating for diffusion of large radicals (Garrod et al. 2008; Oberg et al. 2009b). While the spectra observed to date do not allow for definitive assignments to any specific complex species, the presence of, e.g., a feature at 7.25 μm belonging either to H$_2$COH or CH$_3$CH$_2$OH demonstrates that some complex organic ices are forming efficiently in the prestellar or protostellar stage. The spectra observed to date do not allow for definitive assignments to any specific complex species, the presence of, e.g., a feature at 7.25 μm belonging either to H$_2$COH or CH$_3$CH$_2$OH demonstrates that some complex organic ices are forming efficiently in the prestellar or protostellar stage. The spectra observed to date do not allow for definitive assignments to any specific complex species, the presence of, e.g., a feature at 7.25 μm belonging either to H$_2$COH or CH$_3$CH$_2$OH demonstrates that some complex organic ices are forming efficiently in the prestellar or protostellar stage. The spectra observed to date do not allow for definitive assignments to any specific complex species, the presence of, e.g., a feature at 7.25 μm belonging either to H$_2$COH or CH$_3$CH$_2$OH demonstrates that some complex organic ices are forming efficiently in the prestellar or protostellar stage. The spectra observed to date do not allow for definitive assignments to any specific complex species, the presence of, e.g., a feature at 7.25 μm belonging either to H$_2$COH or CH$_3$CH$_2$OH demonstrates that some complex organic ices are forming efficiently in the prestellar or protostellar stage. The spectra observed to date do not allow for definitive assignments to any specific complex species, the presence of, e.g., a feature at 7.25 μm belonging either to H$_2$COH or CH$_3$CH$_2$OH demonstrates that some complex organic ices are forming efficiently in the prestellar or protostellar stage. The spectra observed to date do not allow for definitive assignments to any specific complex species, the presence of, e.g., a feature at 7.25 μm belonging either to H$_2$COH or CH$_3$CH$_2$OH demonstrates that some complex organic ices are forming efficiently in the prestellar or protostellar stage. The spectra observed to date do not allow for definitive assignments to any specific complex species, the presence of, e.g., a feature at 7.25 μm belonging either to H$_2$COH or CH$_3$CH$_2$OH demonstrates that some complex organic ices are forming efficiently in the prestellar or protostellar stage.
4.4. Ice Evolution in Disks?

The protostellar stage includes the formation of an accretion disk, which is the formation site of planetesimals and eventually planets. These disks are observed to have cold midplanes, where ices should be abundant. It is often difficult to study these disk ices directly because of confusion between disk ices and ices in foreground clouds (Pontoppidan et al. 2005). Comets in our own solar system should, however, carry a record of the ice composition in one such disk midplane. It is unknown whether cometary ices reformed in the disk or whether they are at least partly presolar or protosolar; recent models suggest that much of the original ice will in fact survive accretion from the envelope into the disk (Visser et al. 2009). Even if cometary ices originate from protosolar ices, the protostellar and protosolar ice abundance populations are not expected to overlap perfectly, since the comets originate around a single star, whereas the spread in protostellar ices show the differences in ice abundances between different protostars. Assuming that the protosun resembled one of the observed protostars, what can be addressed is the question of whether comet ice abundances are consistent with a protosolar origin or whether additional ice chemistry in the protosolar nebula is required to account for the observed abundances. In light of this, Figure 13 shows a comparison between cometary and low-mass protostellar CH$_3$OH, CH$_4$, and CO abundances with respect to H$_2$O (Biver et al. 2002; Disanti & Mumma 2008, and references therein).

For all three ices, the cometary abundances are well below the median protostellar abundances. If the observed cometary ices are presolar, this comparison implies either that the ice composition in the protosolar envelope was similar to the most carbon-poor ices observed in the protostellar sample, or that some ice abundances with respect to H$_2$O were reduced in the solar nebula. Possible selective ice destruction processes include desorption of the most volatile ices and UV-induced chemistry.

The spread in cometary ice abundances is comparable to the spread found between different protostellar sources, suggestive either of a primordial variation in ice abundances within the protosolar envelope or of ice processing in the solar nebula, or a combination of the two. Once a sample of cometary CO$_2$ ice abundances becomes available, the dominant source of variation should be possible to constrain, since CO$_2$ ice abundances vary little in the protostellar stage. Already, however, the low CH$_4$ abundances do suggest significant ice destruction during the disk stage, through chemistry or selective desorption. Similarly, comets are known to be significantly depleted in nitrogen, and the small number of comets with directly measured NH$_3$/H$_2$O ratios reveal a loss of NH$_3$ compared to low-mass protostars (Kawakita & Mumma 2011 and references therein)—suggesting that the alteration of cometary ices is not specifically related to carbon. For a more complete cometary ice sample, see the upcoming review by Mumma & Charnley (2011).

5. CONCLUSIONS

Large samples of ice sources spanning diverse environments, evolutionary stages and luminosities are necessary both to determine “typical” ice abundances and to identify how ice processes depend on their environment. The main findings from combining the c2d and other ice surveys carried out in a homogenous way are listed below.

1. The CO and CO$_2$ abundance medians relative to H$_2$O are both ∼29% toward low-mass YSOs, while CH$_4$, NH$_3$, and CH$_3$OH are more than a factor of five less abundant.
2. CO$_2$:H$_2$O, CH$_4$, and NH$_3$ abundances vary little with respect to H$_2$O, suggesting co-formation. In contrast, CO:H$_2$O, OCN$^-$, CO$_2$:CO, and CH$_3$OH vary by factors of two to three (lower to upper quartile) with respect to H$_2$O, indicative of a separate formation pathway from H$_2$O ice. Pure CO and CO$_2$ ice abundances vary even more, consistent with their sensitivity to protostellar heating.
3. Ice abundances toward background stars and protostars are similar except for a lack of features associated with ice heating, such as pure CO$_2$ ice, toward background stars. In particular, there is no evidence for a different range of CH$_3$OH and CO$_2$ ice abundances.
4. Protostellar ice abundances in nearby star-forming regions do not vary significantly between different clouds, except for a significantly lower pure CO abundances toward the protostars in Taurus.
5. Compared to low-mass YSOs, ice abundances toward high-mass YSOs are characterized by low levels of CO and CO$_2$ ices, which can be explained by ice heating. Low-mass protostars in the highly irradiated region IC 1396A have typical low-mass protostellar CO$_2$ ice abundances, confirming that the original ice conditions during low- and high-mass star formation are similar.
6. Correlation studies within the low-mass protostellar sample show a close association between CO, CO$_2$:CO, CO:H$_2$O, and the XCN band, supporting the latter’s identification with OCN$^-$.
7. Combining the above information, ice formation can generally be divided into three stages: an early phase driven by atomic hydrogenation reactions in clouds, which are fast compared to cloud core formation timescales of ∼10$^5$ years; a later CO-freezeout-dependent ice formation phase.
which takes place in the prestellar phase; and finally the protostellar phase where thermal and possibly UV processing shape the ice content.

8. Toward both low- and high-mass protostars and toward molecular clouds, an average of 8%–16% of the total C, O, and N are bound up in ices. Toward the most ice-rich source (IRS 51) 60%–80% of the non-refractory C and O are in ices.

9. There is evidence for more complex ices toward both low- and high-mass protostars, e.g., HCOOH, CH3CHO, and/or C2H5OH, but high-resolution spectra toward more sources are required to confirm their presence and quantify their abundances.

Facilities: Spitzer, VLT:Antu, Keck:II

Support for K.I.O. is provided by NASA through a Hubble Fellowship grant awarded by the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., for NASA, under contract NAS 5-26555. Astrochemistry in Leiden is supported by a SPINOZA grant of the Netherlands Organization for Scientific Research (NWO). Support for this work, part of the Spitzer Space Telescope Legacy Science Program, was provided by NASA through contracts 1224608 and 1230779 issued by the Jet Propulsion Laboratory, California Institute of Technology under NASA contract 1407. The W. M. Keck Observatory is operated as a scientific partnership among the California Institute of Technology, the University of California, and the National Aeronautics and Space Administration, and was made possible by the generous financial support of the W. M. Keck Foundation. The authors recognize the cultural role and reverence that the summit of Mauna Kea has within the indigenous Hawaiian community. We are most fortunate to have the opportunity to conduct observations from this mountain. We acknowledge helpful comments from an anonymous referee.

APPENDIX A

OPHIUCHUS NH3 AND CH3OH SPECTRA

Figure 14 shows the acquired Spitzer spectra for the nine YSOs in Ophiuchus that were added to the c2d sample. The

![Figure 14](image-url)
spectra are dominated by a broad silicate feature which is removed by fitting a polynomial to regions free of molecular emission and absorption. We used the same fitting regions as in Paper IV to determine the ice band depths and shapes and then shifted the regions by \(\sim 0.1 \mu m\) to determine the sensitivity of the results to the chosen local continuum.

The resulting optical depth spectra are shown in Figure 15. CH\(_3\)OH ice is detected toward Elias 32, IRS 42, IRS 51, and VSSG 17; and NH\(_3\) ice is detected toward IRS 44, IRS 46, IRS 51, IRS 63, and WL 6. The bands are fitted with Gaussians and the derived peak positions and full width at half-maxima (FWHM) are listed in Table 6. The uncertainties are dominated by the choice of local continuum. The NH\(_3\) peak positions are consistent with laboratory ice spectra, while the FWHM
Figure 18. Histograms of CO and CO$_2$ components, otherwise as in Figure 17. (A color version of this figure is available in the online journal.)

APPENDIX B
CARRIERS OF THE 7.25 μm ICE FEATURE

Paper I showed that it is difficult to fit the 7.25 μm with spectra of HCOOH, its most commonly assigned carrier. Laboratory spectra of some tertiary mixtures come closest, but suffer from uncertainties in baseline determinations (see below).

Figure 16 shows the spectra of pure HCOOH ice and an H$_2$O:HHCOOH 4:1 ice mixture at 15 K from Bisschop et al. 2007, pure CH$_3$CH$_2$OH and CH$_3$CHO spectra (Öberg et al. 2009b), and observed spectra toward W33A, NGC 7538 IRS 9, and B1-b. W33A and B1-b clearly have absorption features at 7.25 and 7.4 μm, while NGC 7538 IRS 9 does not. The comparison shows that CH$_3$CH$_2$OH is a plausible carrier for the 7.25 μm feature, commonly assigned to HCOOH. The lack of the 7.25 μm toward NGC 7538 IRS 9 is consistent with the upper limit on CH$_3$CH$_2$OH ice from the 3 μm feature (Boudin et al. 1998), while no such limits are published for the other sources. Figure 16 also shows that the observed 7.40 μm feature is likely due to CH$_3$CHO. Thus, there is also little evidence for HCOO$^-$—both have been proposed previously as carriers (e.g., Schutte et al. 1999; Gibb et al. 2004; Paper I).

These tentative identifications may in the future provide an opportunity to observe a complex ice chemistry in situ, but the Spitzer/IRS spectra are too low in spectral resolution to securely distinguish between different carriers, especially since the HCOOH spectral feature depends on the ice matrix and has been reported to become as narrow as the CH$_3$CH$_2$OH band in mixtures with H$_2$O and CH$_3$OH, but this result depends crucially on the choice of local baseline (Bisschop et al. 2007).

Until the HCOOH baseline issue has been resolved and higher resolution spectra exist for more sources, the HCOOH and HCOO$^-$ abundances should not be determined from the 7.25 and 7.42 μm ice features. This does not imply that HCOOH and HCOO$^-$ are not present in interstellar ices, only that we do not currently have the tools to quantify their abundances.

APPENDIX C
HISTOGRAMS OF ICE DETECTIONS AND DETECTIONS + UPPER LIMITS

Histograms of total ice abundances toward low- and high-mass protostars, histograms of CO and CO$_2$ components, and histograms of 5–7 μm components are shown in Figures 17–19, respectively.
