A Renormalization group approach for highly anisotropic 2D Fermion systems:
application to coupled Hubbard chains

S. Moukouri
Department of Physics and Michigan Center for Theoretical Physics
University of Michigan, 2477 Randall Laboratory, Ann Arbor MI 48109

I apply a two-step density-matrix renormalization group method to the anisotropic two-dimensional Hubbard model. As a prelude to this study, I compare the numerical results to the exact one for the tight-binding model. I find a ground-state energy which agrees with the exact value up to four digits for systems as large as 24 × 25. I then apply the method to the interacting case. I find that for strong Hubbard interaction, the ground-state is dominated by magnetic correlations. These correlations are robust even in the presence of strong frustration. Interchain pair tunneling is negligible in the singlet and triplet channels and it is not enhanced by frustration. For weak Hubbard couplings, interchain non-local singlet pair tunneling is enhanced and magnetic correlations are strongly reduced. This suggests a possible superconductive ground state.

I. INTRODUCTION

Quasi-one dimensional organic1 and inorganic2 materials have been the object of an important theoretical interest for the last three decades. The essential features of their phase diagram may be captured by the anisotropic Hubbard model (AHM),

\[ H = -t_\perp \sum_{i,l,\sigma} (c_{i,l,\sigma}^\dagger c_{i+1,l,\sigma} + h.c.) + U \sum_{i,l} n_{i,l,\uparrow} n_{i,l,\downarrow} \]

\[ + V \sum_{i,l,\sigma} n_{i,l,\sigma} n_{i+1,l,\sigma} - \mu \sum_{i,l,\sigma} n_{i,l,\sigma} \]

\[ - t_\parallel \sum_{i,l,\sigma} (c_{i,l,\sigma}^\dagger c_{i+1,\sigma} + h.c.) \]

or a more general Hubbard-like model including longer range Coulomb interactions. The indices \( i \) and \( l \) label the sites and the chains respectively. For these highly anisotropic materials, \( t_\perp \ll t_\parallel \). Over the years, the AHM has remained a formidable challenge to condensed-matter theorists. Some important insights on this model or its low energy version, the g-ology model, have been obtained through the work of Bourbonnais and Caron3 and others. They used a perturbative renormalization group approach to analyze the crossover from 1D to 2D at low temperatures. More recently, Biermann et al.4 applied the chain dynamical mean-field approach to study the crossover from Luttinger liquid to Fermi liquid in this model. Despite this important progress, crucial information such as the ground-state phase diagram, or most notably, whether the AHM displays superconductivity, are still unknown. So far it has remained beyond the reach of numerical methods such as the exact diagonalization (ED) or the quantum Monte Carlo (QMC) methods. ED cannot exceed lattices of about 4 × 5. It is likely to remain so for many years unless there is a breakthrough in quantum computations. The QMC method is plagued by the minus sign problem and will not be helpful at low temperatures. The small value of \( t_\perp \) implies that, in order to see the 2D behavior, it will be necessary to reach lower temperatures than those usually studied for the isotropic 2D Hubbard model. Hence, even in the absence of the minus sign problem, in order to work in this low temperature regime, the QMC algorithm requires special stabilization schemes which lead to prohibitive cpu time.6

II. TWO-STEP DMRG

I have shown in Ref. 7 that this class of anisotropic models may be studied using a two-step density-matrix renormalization group (TSDMRG) method. The TSDMRG method is a perturbative approach in which the standard 1D DMRG is applied twice. In the first step, the usual 1D DMRG method7 is applied to find a set of low lying eigenvalues \( \epsilon_n \) and eigenfunctions \( |\phi_n| \) of a single chain. In the second step, the 2D Hamiltonian is then projected onto the basis constructed from the tensor product of the \(|\phi_n|\)'s. This projection yields an effective one-dimensional Hamiltonian for the 2D lattice,

\[ \tilde{H} \approx \sum_{|n|} E_{|||n|} |\Phi_{|||n|}\rangle \langle \Phi_{|||n|}| - t_\perp \sum_{i,l,\sigma} (\tilde{c}_{i,l,\sigma}^\dagger \tilde{c}_{i+1,l,\sigma} + h.c.)(2) \]

where \( E_{|||n|} \) is the sum of eigenvalues of the different chains, \( E_{|||n|} = \sum_i \epsilon_{n_i} \); \(|\Phi_{|||n|}\rangle = |\phi_{n_1}| \otimes \cdots \otimes |\phi_{n_L}|\) is the corresponding eigenstates, \( c_{i,l,\sigma} \) and \( \tilde{c}_{i,l,\sigma} \) are the renormalized matrix elements in the single chain basis. They are given by

\[ (\tilde{c}_{i,l,\sigma})^n_{m} = (-1)^n \langle \phi_{m_i} | c_{i,l,\sigma}^\dagger | \phi_{n_i} \rangle, \]

(3)

\[ (\tilde{c}_{i,l,\sigma})^{n_i}_{m} = (-1)^{n_i} \langle \phi_{n_i} | c_{i,l,\sigma} | \phi_{m_i} \rangle, \]

(4)

\[ (\tilde{\eta}_{i,l,\sigma})^{n_i}_{m} = \langle \phi_{n_i} | n_{i,l,\sigma} | \phi_{m_i} \rangle, \]

(5)

where \( n_i \) represents the number of fermions from sites 1 to \( i - 1 \). For each chain, operators for all the sites are stored in a single matrix
Since the in-chain degrees of freedom have been integrated out, the interchain couplings are between the block matrix operators in Eqs. (6, 7) which depend only on the chain index \( l \). In this matrix notation, the effective Hamiltonian is one-dimensional and it is also studied by the DMRG method. The only difference compared to a normal 1D situation is that the local operators are now \( m_s^2 \times m_s^2 \) matrices, where \( m_s^2 \) is the number of states kept during the second step.

The two-step method has previously been applied to anisotropic two-dimensional Heisenberg models. In Ref. 8, it was applied to the \( t - J \) model but due to the absence of an exact result in certain limits, it was tested against ED results on small ladders only. A systematic absence of an exact result in certain limits, it was tested extended to the interacting case, before presenting the results up to the fourth digit even if \( \Delta \) \( \epsilon/t \) is larger \( \Delta \) \( \epsilon/t \) for the tight-binding model than for the Heisenberg model, studied in Ref. 7, than \( \Delta \) \( \epsilon/t \) in the anisotropic spin one-half Heisenberg model.

For the tight-binding model, the chains remain disconnected if \( t_\perp < \epsilon_0(N_x + 1) - \epsilon_0(N_x) \) or \( t_\perp < \epsilon_0(N_x) - \epsilon_0(N_x - 1) \), where \( N_x \) is the number of electrons on single chain. In order to observe transverse motion, it is necessary that at least \( t_\perp \geq \epsilon_0(N_x + 1) - \epsilon_0(N_x) \) and \( t_\perp \geq \epsilon_0(N_x) - \epsilon_0(N_x - 1) \). These two conditions are satisfied only if \( \mu \) is appropriately chosen. The values listed in Table (I) corresponds to \( \mu = (\epsilon_0(N_x + 1) - \epsilon_0(N_x - 1))/2 \). This threshold varies with \( L \). I give in Table (I) the values of \( t_\perp \) chosen for different lattice sizes. In principle, for the TSDMRG to be accurate, it is necessary that \( \Delta \epsilon = \epsilon_{n_x} - \epsilon_0 \), where \( \epsilon_{n_x} \) is the cut-off, be such that \( \Delta \epsilon/t_\perp \gg 1 \). But in practice, I find that I can achieve accuracy up to the fourth digit even if \( \Delta \epsilon/t_\perp \approx 5 \) using the finite system method. Five sweeps were necessary to reach convergence. Note that this conclusion is somewhat different from my earlier estimate of \( \Delta \epsilon/t_\perp \approx 10 \) for spin systems. This is because in Ref. 8, I used the infinite system method during the second step.

The ultimate success of the TSDMRG depends on the density of the low-lying states in the 1D model. For fixed \( m_s^2 \) and \( L \), it is, for instance, easier to reach larger \( \Delta \epsilon/J_\perp \) in the anisotropic spin one-half Heisenberg model, studied in Ref. 7, than \( \Delta \epsilon/t_\perp \) for the tight-binding model as shown in Fig (1). For \( L = 16, m_s^2 = 96 \), and \( J_\perp = t_\perp = 0.15 \), I find that \( \Delta \epsilon/J_\perp \approx 10 \), while \( \Delta \epsilon/t_\perp \approx 5 \). Hence, the TSDMRG method will be more accurate for a spin model than for the tight-binding model. Using the infinite system method during the second step on the anisotropic Heisenberg model with \( J_\perp = 0.1 \), I can now reach an agreement of about \( 10^{-6} \) with the stochastic QMC method.

Two possible sources of error can contribute to reduce the accuracy in the TSDMRG with respect to the conven-
chain having the effective single site during the second step is now a very large, in this case it is about 5, to obtain very

matrix. The construction of the reduced density matrix is

a workstation.

are nevertheless very good given the relatively modest

reduction in accuracy of about two orders of magnitude

Table (III), it can be seen that this results in a

just the coordinates of the superblock wave function

basis of E and F respectively. Then, \(|l\rangle\) has a dual basis

such that \(\langle l'\rangle|l\rangle = \delta_{l'l} R\). The matrix elements of \(u_F\)
in this basis are the reduced density matrix. Table (IV), I show

the improved energies when, besides the ground state, I target the lowest states of the spin sectors \(S_z = -1\) and \(S_z = +1\) with \(N\) electrons. The weights were respectively 0.995, 0.0025, and 0.0025 for the three states. This lowers \(E_0(N)\) in all cases, but the gain does not appear to be spectacular. But I do not know whether this is due to my choice of perturbation of \(\rho\) or whether even the algorithm with four blocks would not yield better \(E_0(N)\). If the lowest sectors with \(N + 1\) and \(N - 1\)
electrons which have \(S_z = \pm 0.5\) are projected instead, I find that the results are similar to those with \(S_z = \pm 1\) sectors, there are possibly many ways to add the missing states. A more systematic approach to this problem has recently been suggested. It is based on using a local perturbation to build a correction to the density matrix from the site at the edge of the system. Here, such a perturbation would be \(\Delta \rho = \alpha c_0^\dagger \rho c_1\), where \(\alpha\) is a constant, \(\alpha \approx 10^{-3} - 10^{-2}\), and \(c_0^\dagger, c_1\) are the creation and annihilation operators of the chain at the edge of the system. This type of perturbation resulted in an accuracy gain of more than an order of magnitude in the case of a spin chain. The three block method was found to be on par with the four block method. It will be interesting to see in a future study how this type of local perturbation performs within the TSDMRG.

To conclude this section, as a first step to the investigation of interacting electron models, I have shown that the TSDMRG can successfully be applied to the tight-binding model. The agreement with the exact result is very good and can be improved since the computational power involved in this study was modest. The extension

may be regarded as a linear mapping \(u_F : F^* \rightarrow E\), where \(E\) is the system, \(F\) is the environment and, \(F^*\) is the dual space of \(F\). Using the decomposition of the superblock wave function \(\Psi_{[0]} = \sum_i \phi_i^L \otimes \phi_i^R\), with \(\phi_i^L \in E\) and \(\phi_i^R \in F\), for any \(\phi^* \in F^*\),

\[
\sum_{i=1}^r \langle \phi^* | \phi_i^R \rangle \phi_i^L. \quad (10)
\]

Let \(|k\), \(k = 1, \ldots, \text{dimE}\) and \(|l\rangle\), \(l = 1, \ldots, \text{dimF}\) be the basis of \(E\) and \(F\) respectively. Then, \(|l\rangle\) has a dual basis \(\langle l'|\rangle\) such that \(\langle l'|l\rangle = \delta_{l'l} R\). The matrix elements of \(u_F\) in this basis are just the coordinates of the superblock wave function \(\Psi_{[0]}|l\rangle\). The rank \(r\) of this mapping, which is also the rank of the reduced density matrix is always smaller or equal to the smallest dimension of \(E\) or \(F\), \(r < \text{Min}(\text{dimE}, \text{dimF})\). Hence, if \(m_{S_2}\) states are kept in the two external blocks, the number of non-zero eigenvalues of \(\rho\) cannot be larger than \(m_{S_2}\). Consequently, some states which have non-zero eigenvalues in the normal four block configuration will be missing. A possible cure to this problem is to target additional low-lying states above \(\Psi_{[0]}(N)\). The weight of these states in \(\rho\) must be small so that their role is simply to add the missing states not to be described accurately themselves. A larger weight on these additional states would lead to the reduction of the accuracy for a fixed \(m_{S_2}\). In Table (IV), I show the improved energies when, besides the ground state, I target the lowest states of the spin sectors \(S_z = -1\) and \(S_z = +1\) with \(N\) electrons. The weights were respectively 0.995, 0.0025, and 0.0025 for the three states. This lowers \(E_0(N)\) in all cases, but the gain does not appear to be spectacular. But I do not know whether this is due to my choice of perturbation of \(\rho\) or whether even the algorithm with four blocks would not yield better

**IV. GROUND-STATE PROPERTIES OF COUPLED HUBBARD CHAINS**

I now proceed to the study of $U \neq 0$. One of the main motivations for such a study is the possibility to gain insight into the mechanism of superconductivity in quasi 1D systems. The mechanism of superconductivity in the quasi 1D organic materials Bechgaard and Fabre salts, is still an open issue. Since these materials are 1D above a crossover temperature $T_c \approx t_\perp / \pi$, it is broadly accepted that the starting point for the understanding of their low $T$ behavior should be pure 1D physics. The occurrence of the low $T$ ordered phases is driven by the interchain hopping $t_\perp$. Two main hypotheses have been suggested concerning superconductivity. The first hypothesis (see a recent review in Ref. 13) relies on a more conventional physics: $t_\perp$ drives the system to a 2D electron gas which is an anisotropic Fermi liquid which becomes superconductive through a conventional BCS mechanism. However, it has been argued that given the smallness of $t_\perp$, the resulting electron-phonon coupling would not be enough to account for the observed $T_c$. The second hypothesis, which has gained strength over the years given the absence of a clear phonon signature, is that the pairing mechanism originates from an exchange of spin fluctuation.

Interest in this issue was recently revived by the NMR Knight shift experimental finding that the symmetry of the Cooper pairs is triplet\cite{14} in $(TMTSF)_2(PF_6)$. No shift was found in the magnetic susceptibility at the transition for measurement made under a magnetic field of about 1.4 Tesla. A triplet pairing scenario was subsequently supported by the persistence of superconductivity under fields far exceeding the Pauli breaking-pair limit\cite{15}. However there is no simple explanation of this scenario. Triplet pairing would be unfavorable in a BCS like scenario for which a singlet s-wave is most likely. Triplet pairing is also less likely in the spin fluctuation mechanism for which a singlet d-wave is predicted by analytical RG\cite{16} or by perturbative approaches\cite{17}. It has be argued that these difficulties in both mechanisms can be circumvented. In the BCS case, the association of AFM fluctuations with an open Fermi surface to the electron-phonon mechanism may lead to a triplet pairing\cite{18}. In the spin fluctuation case, the addition of interchain Coulomb interactions may favor a triplet f-wave in lieu of the singlet d-wave\cite{19}. The more exotic Fulde-Ferrel-Larkin-Ovchinnikov phase can also been invoked to account for the large paramagnetic limit. However, the Knight shift result which was thought to bring a conclusion to this long standing issue has only revived the old controversy. The conclusion of this experiment itself has been recently challenged. In Ref. 15 it was pointed out that the observation of triplet superconductivity claimed in Ref. 12 could be a spurious effect due to the lack of thermalization of the samples. A recent Knight shift experiment performed at lower fields reveals a decrease in the spin susceptibility. This is consistent with singlet pairing.\cite{20}
The 1D interacting electron gas is now fairly well understood. There is no phase with long range order. There are essentially four regions in the phase diagram, characterized by the dominant correlations: CDW, charge density wave (CDW), singlet superconductivity (SS) and triplet superconductivity (TS). The essential question is whether the interchain hopping will simply freeze the dominant 1D fluctuation into long-range order (LRO) or create new 2D physics. The estimated values of $U$ and $V$ for the Bechgaard salts suggest that they are in the SDW region in their 1D regime. This suggests that superconductivity in these materials is a 2D phenomenon. Interchain pair tunneling was suggested soon after the discovery of superconductivity in an organic compound. Emery argued instead that a mechanism similar to the Kohn-Luttinger mechanism might be responsible for superconductivity in the organic materials. When $t_\perp$ is turned on, pairing can arise from exchange of short-range SDW fluctuations. The reason is that the oscillating SDW susceptibility at $Q = (2k_F, k_\perp)$ would have an attractive region if $k_\perp \neq 0$. In particular if $k_\perp = \pi$ as I found, then the interaction would be attractive between particles in neighboring chains. In this study, I will restrain myself to the study of interchain pair tunneling. I was unable to compute correlation functions of pairs in which each electron belongs to a different chain. The reason is that in the DMRG method, for the correlation functions to be accurate, at least two different blocks should be involved. This means that for pair correlation for which each electron of the pair is on a different chain, at least four blocks are needed. However, the introduction of four blocks in the second step of the TSDMRG leads to a prohibitive CPU time.

With the hope of frustrating an SDW ordering which is usually expected, I will add an extra terms to model. These are the diagonal interchain hopping,

$$ H_d = -t_d \sum_{i,l,\sigma} \langle c_{i,l,\sigma}^\dagger c_{i+1,l+1,\sigma} + h.c. \rangle $$

and the next-nearest neighbor interchain hopping,

$$ H_\perp = -t_\perp \sum_{i,l,\sigma} \langle c_{i,l,\sigma}^\dagger c_{i+2,l+2,\sigma} + h.c. \rangle. $$

I will also add the interchain Coulomb interaction,

$$ H_V = V_\perp \sum_{i,l,\sigma} n_{i,l,\sigma} n_{i+1,l+1,\sigma}. $$

I set $t_\perp = 0.2$, $m_{s1} = 256$, $m_{s2} = 128$, and $(L \times (L + 1) = 16 \times 17$. A second set of calculations with $t_\perp = 0.15$, same values of $m_{s1}$ and $m_{s2}$, and $(L \times (L + 1) = 24 \times 25$ lead to the same conclusions. Therefore, they will not be shown here. In order to analyze the physics induced by the transverse couplings, I compute the following interchain correlations: the transverse single-particle Green’s function, shown in Fig.4

$$ C(y) = \langle c_{L/2,L/2+y}^\dagger c_{L/2,L/2+1} \rangle; $$

the transverse spin-spin correlation function, shown in Fig.5

$$ SS(y) = \langle \Sigma_{L/2,L/2+y}^\dagger \Sigma_{L/2,L/2+1} \rangle; $$

where

$$ \Sigma_{i,l} = c_{i,l}^\dagger c_{i,l}. $$
the transverse triplet superconductive correlation, shown in Fig.6

\[ ST(y) = 2(\Theta_{L/2,L/2+y}^{\dagger} \Theta_{L/2,L/2+1}^{\dagger}) \]  

where

\[ \Theta_{i,l}(c_{i,l}^\dagger c_{i+l,l}^\dagger + c_{i,l} c_{i+1,l}^\dagger) \]  

and the transverse non-local singlet pair superconductive correlation function, shown in Fig.7

\[ SD(y) = 2(\Delta_{L/2,L/2+y}^{\dagger} \Delta_{L/2,L/2+1}^{\dagger}) \]  

where

\[ \Delta_{i,l} = \frac{1}{\sqrt{2}}(c_{i,l} c_{i+1,l}^\dagger - c_{i,l}^\dagger c_{i+1,l}^\dagger) \]  

A. Strong-coupling regime

Let us first consider, the regime \( U \gg 4 \), I choose for instance \( U = 4 \), \( V = 0.85 \), \( \mu = 0 \), and \( t_d = t_s^0 = V_\perp = 0 \); besides single-particle hopping, \( t_\perp \) also generates two-particle hopping both in the particle-hole and particle-particle channels. These two-particle correlation functions are roughly given by the average values \( t_s^2 \langle c_{i,l+\sigma} c_{i,l+\sigma} c_{i+1,l+\sigma} c_{i+1,l+\sigma}^{\dagger} \rangle \) and \( t_\perp^2 \langle c_{i,l}^\dagger c_{i+1,l} c_{i,l+1} c_{i+1,l+1}^{\dagger} \rangle \) for an on-site pair created at \((i,l)\) and then destroyed at \((i,l + j)\). It is expected that the dominant two-particle correlation are SDW with \( k_\perp = \pi \). This is seen in Fig.7. The transverse pairing correlations are all found to be small with respect to \( C(y) \). Among the pairing correlations, \( SS(y) \) decays faster then \( ST(y) \) and \( SD(y) \). These results are consistent with the view that the role of \( t_\perp \) is to freeze the dominant 1D correlations into LRO.

When \( t_d \neq 0 \), it is expected that for a strong enough \( t_d \), the magnetic order will vanish because of the frustration induced by \( t_d \). A simple argument is that \( t_d \) induces an AFM exchange between next-nearest neighbors on chains \( l \) and \( l + 1 \) which compete with the AFM exchange between nearest neighbors. The hope is that there could be a region of the phase diagram where superconductivity could ultimately win either by pair tunneling between the chains or by the Emery’s mechanism. However, in Fig.7 it can be seen that, while \( t_d \) slightly reduces \( C(y) \), the dominant correlations are still SDW even for a strong \( t_d/t_s = 0.5 \). \( SS(y), ST(y) \) and \( SD(y) \) are barely affected by \( t_d \). The fact that \( t_d \) does not strongly affect the SDW order can be understood in the light of recent study of coupled \( t-J \) chains\(^5\). It was shown that the frustration strongly suppresses magnetic LRO only close to half-filling. For large dopings, two neighboring spins in a chain do not always points to opposite direction as the consequence, \( t_d \) does not necessarily frustrate the magnetic order. This is illustrated in a simple sketch in Fig.8. \( t_d \) could even enhance it as seen in the study of \( t-J \) chains. In Fig.8 it can be seen that \( t_d \) enhances \( G(y) \). This enhancement, together with the decrease of \( C(y) \), suggests a possible widening of an eventual Fermi liquid region at finite \( T \) above the ordered phase. When \( t_\perp \neq 0 \), I also found (not shown) that magnetic correlation are not effectively suppressed even when \( t_\perp = t_\perp \). For this value, it would be expected that the ratio of the effective exchange term generated by \( t_\perp \) to that generated by \( t_\perp = t_\perp \) is about one quarter. In the frustrated \( J_1 - J_2 \) spin chain, a spin gap opens around this ratio. This simple picture does not seem to work here.
FIG. 8: sketch of the spin texture (arrows) in two consecutive chains in an SDW. The bold horizontal lines represent the chains. The full diagonal lines show bonds for which $t_d$ tends to increase the SDW order. The diagonal dotted lines show bonds for which $t_d$ frustrates the magnetic order.

B. Weak-coupling regime

I now turn in to the regime where $U \lesssim 4$. I set $U = 2$, $V = 0$, $\mu = -0.9271$, $t_\perp = 0.2$, $t_d = 0$, and $V_\perp = 0.4$, where $V_\perp$ is the interchain Coulomb interaction between nearest neighbors. It can be seen in Fig. 9 that $C(y)$ is now strongly reduced with respect to its strong coupling values. It is already within our numerical error for the next-nearest neighbor in the transverse direction. This is an indication that the ground state is probably not an SDW. It is to be noted that this occurs even in the absence of $t_d$ or $t'_\perp$. This seems to be at variance with the RG analysis which requires $t'_\perp$ to destroy the magnetic order. A possible explanation of this is that at half-filling the perfect nesting occurs at the wave vector $Q = (\pi, \pi)$ for the spectrum of equation (9). Away from half-filling the nesting is no longer perfect this leads to the reduction of magnetic correlations. The first correction to the nesting is an effective frustration term which is roughly $t_\perp^2 \cos 2k_\perp$. This expression is identical to a term that could be generated by an explicit frustration $t'_\perp = t_\perp^2$. The discrepancy between the TSDMRG and the RG results could be that this nesting deviation is underevaluated in the RG analysis. This mechanism cannot be invoked in the strong coupling regime where band effects are small.

The suppression of magnetism is concomitant to a strong enhancement of the singlet pairing correlations as seen in Fig. 11. Triplet correlations, shown in Fig. 10, remain very small. However, while it is clear from the behavior of $C(y)$ that the ground state is non magnetic, this result strongly suggests that the ground state is a superconductor in this regime. A finite size analysis is, however, necessary to conclude whether this persists to the thermodynamic limit. I cannot rule out the possibility of a Fermi liquid ground state, which is implied by strong single particle correlations.

V. CONCLUSION

In this paper, I have presented a TSDMRG study of the competition between magnetism and superconductivity in an anisotropic Hubbard model. I have analyzed the effect of the interchain hopping in the strong and weak $U$ regimes. In the strong-coupling regime, the results are consistent with earlier predictions that the role of $t_\perp$ is to freeze the dominant 1D SDW correlations into a 2D ordered state. But at variance with analytical predictions, this is only true in the strong $U$ regime. In this regime, I find that even the introduction of frustration does not disrupt the SDW order which remain robust up to large values of the frustration. In the weak coupling regime singlet pair correlations are dominant. The ground state seems to be a superconductor. This behavior is somewhat in agreement with experiments in the Bechgaard or Fubre salts. The phase diagram is domi-
 FIG. 11: Transverse singlet non-local superconductive correlation $SD(y)$ for $U = 4$ (circles), $U = 2$ and $V_{\perp} = 0.4$ (squares).

I am very grateful to C. Bourbonnais for very helpful exchanges. I wish to thank A.M.-S. Tremblay for helpful discussions. This work was supported by the NSF Grant No. DMR-0426775.
